Touching upon this question of the ability of typhoid germs to withstand freezing, the instance of the epidemic at Plymouth, Pa., is a case in point. There the dejecta of a patient lay frozen upon a hillside from January until March, when they were washed by the melting snow into the city water system with most disastrous results.

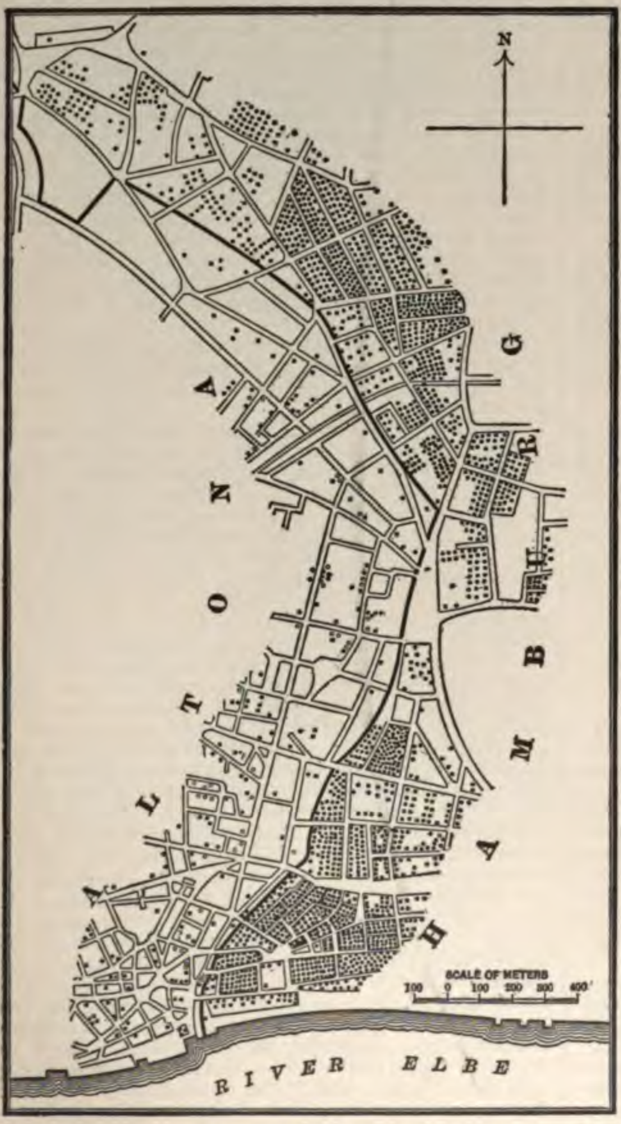

FIG. 5031.—Chart showing Distribution of Cholera Cases, in the Epidemic of 1892, at Hamburg and Altona. ▬, Boundary between the two cities; •, cases of cholera; ∘, cases imported from Hamburg.

Stress should be laid upon the fact that the large percentage of bacterial purification which results from freezing, as above referred to, is due to the mechanical exclusion of suspended particles by the growing crystals and not to a mere lowering of temperature. Even the intense cold of liquid air is but indifferently germicidal.

Beyond the ordinary wash caused by storms upon every water-shed, some rivers are exposed to sudden and great concentration of pollution through the sweeping away of piles of filth which accumulate upon their rocky fore-shores during periods of low water. The Tees, a river of northern England, is of such description. A study of the epidemic of typhoid which prevailed in that valley in 1891 proved of special interest, because the disease confined itself to those communities, aggregating 220,000 people, who used the river water, to the exclusion of a population of 280,000 of the same district who drank water from other sources.

A further point of interest lay in the striking manner in which a chart of the reported cases showed a rise in the number of fever patients about fourteen days after each heavy rainfall. (Fig. 5032.)

Streams in Europe are frequently polluted by the washing therein of infected linen, an out-of-doors laundry being common enough in the Old World, although quite the reverse in America. To such a cause was ascribed the great cholera outbreak at Messina in 1887, and a like epidemic at Cuneo in 1884 was traced to an entirely similar source.

"Deep-seated" is a term applied to water of a distant origin to distinguish it from "ground water" of an entirely local source.

Springs of small flow, such as trickle out of the country hillside, are properly classified with shallow wells; they furnish "ground water" only and are of local origin.

Quite another matter, however, are those natural fountains which reach the surface in great volume, possessed of a temperature radically different from that of the local subsoil, and holding in solution mineral materials that may be quite foreign to the neighborhood. Such water is always of distant source, and the gathering grounds where it originally falls as rain may be very far away indeed.

Picture the outcrop upon some rainy upland of a porous stratum, encased upon either side by strata impervious to water; let the strata be possessed of a moderate dip, then let them be cut transversely at some point below, either by simple erosion or by a geologic fault, and the conditions for a deep-seated spring would be complete. Rain water falling on the distant outcrop would pass down the porous stratum, picking up soluble material on the way, and would escape as a spring at the point where the strata were broken or eroded.

At the head of San Antonio River, not far from the city of San Antonio, Tex., is situated a mammoth spring of pure water, whose daily outflow is some fifty million gallons. This spring is but one of a group of great springs which "coincide almost exactly with the line of the great Austin Del Rio fault." A very curious instance of a spring of great magnitude caused by erosion cutting into the water-bearing stratum is to be found several miles out at sea off the coast of Florida, east of Matanzas Inlet.

There are reasons for believing that the Matanzas spring is due to a bursting of the confined waters through a hole in the upper hard rock layer. Successful sounding has recently been accomplished in the spring itself. In its immediate vicinity the ocean suddenly deepens from a depth of sixty to one of one hundred and twenty-six feet.

Instances are by no means rare of the use of deep springs for water supplies of magnitude, such as the "Vanne" water, which supplies a part of Paris from springs in massive chalk near Troyes, but deep seated water is much more commonly reached by special borings.

The expression "artesian" has been extended to include deep wells under all conditions, but without proper license, because the term originally came from the name of the French province where deep wells were first successfully established, and such wells were "flowing." It is therefore to "flowing wells" only that the expression "artesian" properly attaches. Wells of this class were first sunk, in Europe, at Lillers, in Artois, in 1126. In the Sahara and in China they have been known for many centuries. Whether, however, the well be a flowing one or one from which the water has to be raised by power, the conditions governing the storage of such water are essentially the same as have been already given when speaking of deep springs. An outcrop of a porous stratum in a rainy upland acts as the collecting area; this stratum is of moderate dip and is enclosed by other strata, impervious to water, lying above and below.

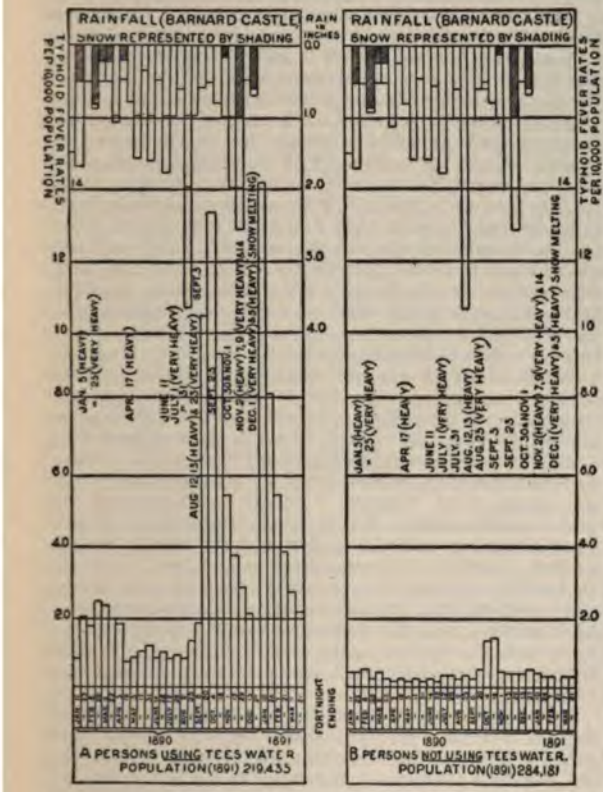

FIG. 5032.—Rainfall and Typhoid Fever in the Tees Valley, England.

Unless the strata form a basin or pocket, the water of the porous layer will find its natural outlet in a spring form where the layer is cut transversely by erosion or fault; but should a well be sunk at some intermediate point the water will rise in the same, or overflow, to a degree dependent upon the head to which it is subjected; that is, to the elevation of the gathering grounds above the well, and to the freedom with which the water can flow down the porous stratum and escape through the outlets below. (Figs. 5033 and 5034.)

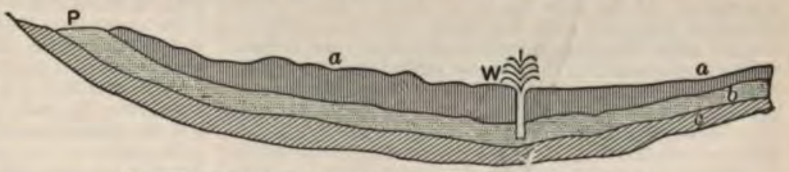

FIG. 5033.—Condition Favorable for Flowing Well. (After Hay.)

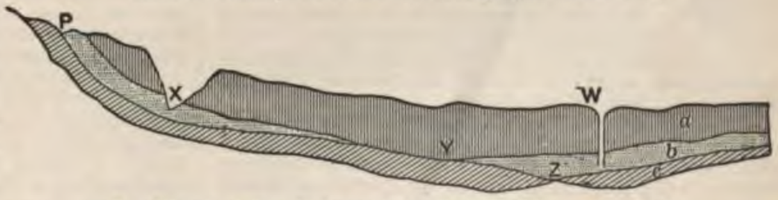

FIG. 5034.—Condition Unfavorable for Flowing Well. (After Hay.)

It must be remembered in this connection that the expression "deep" refers to the non-local character of the water rather than to the depth of the hole required for tapping the same. In fact, "deep water" may lie very near the surface in some places.

Contrary to the belief of many people, deep-seated water is not inexhaustible. If the porous layers containing it be extensive, an immediately available supply of large volume, which is the accumulation perhaps of ages, may be counted upon; but should the daily drain be larger than the natural reinforcement, the delivery must surely shrink in quantity and finally cease.

It is common knowledge that a great volume of water, some sixty-six million United States gallons, is drawn daily by the London water companies from deep wells in the chalk.

The serious effect of extending and heavily pumping these deep chalk wells supplying a portion of London is that "for every two gallons of water collected within the Lee valley London is withdrawing three from its reservoir in that chalk basin, and this quite apart from the amount every day required by the resident population of that area. The result of such a process can only be a steady, if gradual, exhaustion of water from the chalk and a progressive lowering of its plane of saturation."

Water from deep sources has commonly characteristics of its own, distinguishing it from the ground water of the neighborhood. One of the most easily recognized of these is high temperature.

Another peculiarity of deep water is the small quantity of dissolved oxygen which it usually contains. This is by no means due to the pressure to which it may be subjected, for increase of pressure favors the solution of gases, but is rather owing to the abundant opportunity for removal of oxygen by contact with such substances as organic matter, and compounds of iron and manganese, presented during the long underground journey of the water from its place of collection.

In point of composition the waters of deep wells are almost always highly mineralized, as would be expected in consideration of the items of long time, long distance of flow, high pressure, and elevated temperature. Sometimes the materials contained render the water unfit for use, even for boiler purposes, but more commonly the supply is such as to be considered a great boon to the fortunate possessor.

Perhaps as noteworthy an instance of a flowing well as can be quoted is that of Woonsocket, South Dakota. The boring is of seven inches in diameter and seven hundred and fifty feet deep. The water is of 63° F. temperature and is thrown above the surface to a height of eighty feet in a magnificent fountain, the entire discharge amounting to 11,500,000 gallons per twenty-four hours. The well is capable of furnishing a pressure of one hundred and forty pounds per square inch.

The circulation of the "ground water" in the soil is governed by gravity and surface tension, and the latter is in turn affected by the structure of the soil, its composition, and the per cent. by volume of the empty spaces between its particles.

The rate at which water will flow through a soil is dependent not only upon the aggregate volume of the voids, but also, and more particularly, upon their separate dimensions; for it can be readily seen that the inhibiting influence of friction will rapidly increase with the fineness of the soil grain.

Values are on record for the water-holding powers of various soils, but a word of caution seems proper here. It must be remembered that such figures show what the sands and soils will *hold*, not what they would *deliver*. No pump could extract that final portion of the contained water which would remain as "moisture," and its quantity would be a very respectable percentage indeed of the amounts given.

Wherever found, and under whatever circumstances, the water of the ground owes its origin to the rain or melting snow. Attention is called to this point because of a widespread notion that the wells of fresh water often existing in the immediate vicinity of the ocean are fed with sea water from which the salt has been removed by percolation through the sand of the beach. This inference is permitted in an engineering work of national fame. All along the shore of the Italian Riviera the traveller can see wells dug within one hundred and fifty feet of the surf. In such cases the fresh water found originates some considerable distance inland, and the wells intercept it on its way toward an outlet in the sea; in other instances its origin is due entirely to very local rains, and its storage in the loose sand is owing to its being specifically lighter than the surrounding sea water.

An instance of this kind is met with near the island of Heligoland. About a mile east of the island there is a long strip of sand raised but a few feet above the level of the ocean, extending some half a mile in length and but two hundred yards wide. It was formed and is maintained by ocean currents, and is covered by a scanty growth of grass. Anywhere upon this islet fresh water may be obtained by digging in the sand. Necessarily the water to be secured from such a source is limited in quantity.

A commonly received conception of the occurrence of ground water is that it moves in very definitely localized streams, and that, to be successful, a well must be sunk directly into one of these. Of course the conformation of the country may at times cause this popular notion closely to coincide with the truth, but a more general description of the occurrence of ground water would be that of a widely extended sheet, and the expression "water table" has been adopted with that view in mind.

The mean height of this "water table" (*i.e.*, its distance from the surface of the ground) is governed by the average rainfall and the opportunities for local drainage. The delivery being into the rivers and streams of the district, or into the sea, there is always a slight inclination of the water surface toward those natural drains, more especially in their immediate vicinity.

When the conditions prevailing in the district do not favor the development of a spring on the side or at the base of a slope, the time-honored manner of tapping the underground supply is to sink the ordinary domestic well into the water table.

For the delivery of large supplies the ground water cannot be conveniently tapped by ordinary dug wells, so that recourse is had in such cases to what is known as "driven wells," set within suitable distance of each other, and coupled to a general main through which the water is drawn by the pump.

Each well is but an iron tube, perforated at its lower extremity, which is driven through the soil to the water-bearing layer below. Single wells of this description, surmounted by a simple hand-pump, may be seen, in some instances, replacing the domestic well in the country dooryard, but the type is more commonly met with in "gangs" of very considerable number for the supply of cities or towns.

A method of sinking them by the use of live steam was patented a few years ago, and, under some conditions of soil, may show considerable saving in first cost.

By whatever method the "driven well" is sunk, its mode of action is entirely similar to that of the common domestic well, from which it differs only in diameter, and it is supplied by the ground water of the district in the same manner as its longer-known progenitor. There is, in short, nothing gained in the majority of cases from the supposed exhaustion of air by the action of the pump. Much has been claimed under this head, and it has been urged that the zone of influence always widens rapidly under "suction" from an air-tight well; but it must be remembered that "air-tight" is a term which can be usually applied to the well only, and not to the ground overlying the zone of influence. The porous soil will unquestionably admit all the atmosphere required, and consequently the flow of water will be determined by those forces, and those only, which govern in the case of wells of the ordinary type.

When, however, the well passes through an extensive layer of impervious clay, and taps a water-bearing stratum beneath, then the opportunities for a development of the advantages of "suction" reach their maximum.

A fact often lost sight of is that driven wells, so far as a permanent supply is concerned, are dependent upon the amounts of rainfall, "run-off," evaporation, and plant requirements. There is not, contrary to popular conception, an underground reservoir from which unlimited quantities of water may be pumped. It is true that a reserve storage exists, that may be drawn upon in time of drought, but nature keeps a strict account of such matters, and the deficiency created in time of need must be made up during the period of plenty; otherwise the delivery of the plant will gradually diminish and ultimately entirely cease.

One very material advantage possessed by a driven well over a dug one is that it can be sunk deeper in the water-bearing sands at small expense, and, with a long strainer, can take water throughout a great fraction of its length. A dug well, on the other hand, has its construction hampered after water is reached, and its cost per foot is greater beyond that point; so that it commonly has to depend principally upon its bottom for supply, tapping, as it does, only the upper portion of the ground-water layer.

Closely related to the well systems already spoken of, the "infiltration gallery" stands as a widely used method for securing the water of the ground. Such a gallery is really but a dug well with one very long horizontal axis. Its position is usually near, and parallel to, the banks of some stream, such a site being chosen with a view of securing its supply from the water of the river. Except under exceptional circumstances, however, the water reaching the gallery comes from the landward side, and is the ground water of the district for which the river is the drain.

Rivers may indeed diminish in volume as they flow onward, and may even entirely disappear by sinking into the ground, as is the case with a number of streams flowing down the slopes of the Rocky Mountains, but this condition is distinctly exceptional. A river is commonly to be regarded as a drain, into which water is received, but from which none flows.

Dependence is constantly laid upon the excellent filtering powers of these underground galleries, and they justify it during the earlier periods of their use, but, considered as a filter, such a device is beyond cleaning and repair; it may clog, or, on the other hand, ruinous channelways may follow heavy pumping. In the first instance no water, and in the second instance polluted water, may result.

The opportunity for the contamination of well water, particularly that of the common domestic well, is often very great. No proper conception of the right location for the house well ever seems to enter the minds of most f our rural people, and if water can be had from a spot onveniently near for general housework, inquiry as to he quality of such supply is usually considered quite uperfluous.

In some towns the local boards of health determine the inimum distance to be allowed between a well and an ncemented privy vault, and such distance is most comonly fixed at fifty feet. The permitted distance in at ast one instance is twenty-five feet, and in another the inimum distance allowed is twenty feet!

That any such distance of soil filtration can protect a ell from pollution, provided the polluting source be nstant in character, is beyond even hoping for, and any instances could be given showing how even conderably greater distances have also failed.

Two causes for failure are, first, overtaxing the purifyg powers of the intervening soil by presenting a nstant flow of more polluting material than can be idized, and second, the opening up of cracks in the bsoil whereby direct connection with the well is assured.

The serious Maidstone epidemic of typhoid was due to e latter cause. An unusual drought had occurred, hich caused deep cracks to open in the stiff soil, so ep that the health officer thrust his cane into some of em without finding bottom. Later there was a heavy ll of rain which washed surface filth carrying typhoid creta into these fissures and produced a material rise in e ground water. Of course there was lack of efficient l filtration.

It is a fatal error to fancy that because a water has a ight, sparkling, clear appearance and a pleasant taste, erefore such water is wholesome. Carbonic acid gas what causes the brilliancy and refreshing taste of a ound water, and to the solvent action of that gas is due e clearness of many waters which nevertheless hold ch organic matter in solution. When it is borne in nd that carbonic acid is one of the products of sewage composition, the inference as to its possible source in case of some well waters is not a pleasant one.

It is often objected that certain well waters have been use for many years without bad results following. ssibly; but it must be remembered that the imbibin of sewage derived from healthy sources may be ite harmless, unless it be in too concentrated a form, wever undesirable it may be from an æsthetic standint. The serious part of it all is that the sewage ich contaminates the well water may, during an epinic, suddenly become pathogenic in character, and n the well becomes a distributing centre for disease. ity well is always to be suspected, and if, upon examtion, its water is found impure, it should be forthwith lered closed, particularly under circumstances such as eaten invasion of epidemic disease.

An excellent way to determine the probability of obtionable drainage material entering a well is to place uantity of a solution of common salt, of lithium chloe, or of fluorescein at the point whence contamination supposed to come. The normal composition of the ter being known, there will appear an increase in lorides," a spectroscopic test for lithium, or a decided rescence in the water if there be drainage from the rce in question.

lthough of somewhat uncertain reliability as to ntity, rain water is universally looked upon with ch favor because of its assumed excellence as to qualand yet even a casual inspection will often show it be a long way from pure, and it may possibly be luted to an extent quite surprising to the collector of supply.

he roof upon which rain is caught is a twofold cause impurity in the collected water; first, because of the erial of which the roof is constructed, and, second, ause of the foreign substances that may settle thereon.

cities the amount of street dust blown upon the roof afterward washed into the cistern is much greater n is commonly supposed. Soot, excrement of birds en a large item), fallen leaves, and various mossy growths are among the sundry additions to be found in a roof-collected water.

It is exceedingly important that every cistern should be inspected and cleaned frequently, and upon no point does the public require more instruction than this.

While its softness recommends it for use in the laundry, and while the absence of lime salts renders it desirable for cooking, rain water is, on the whole, not to be considered so suitable as a pure ground or surface water for general domestic supply.

Ice, especially in America, is certainly to be reckoned as an article of food, and the prevalent belief that water purifies itself during the act of freezing is so well fixed in the public mind that the source whence ice is harvested is in consequence usually considered unimportant. This belief is not without support in fact, as we have seen, but, like many another partial truth, it is a very uncertain foundation upon which to erect the best form of sanitary procedure.

As has been already stated, we may depend upon the growing ice crystals mechanically excluding much of the germ life during the process of freezing, and such exclusion would appear to lie between ninety and ninety-five per cent. of all bacteria present in the water, or, more strictly speaking, the above percentages would represent the bacterial purification from all causes during freezing, of which causes mechanical exclusion is one.

ARTIFICIAL PURIFICATION OF WATER.—Pure water is becoming more and more difficult for many of our towns to secure, so that the best that some of them can hope to obtain is a polluted water which has been efficiently purified by art. It is a question, sometimes, whether it would not be better policy, considering the rapid changes in the density of population, to accept a moderately polluted source and thoroughly purify its water, rather than go to large expense in obtaining a faultless supply which might have to be purified in its turn at some later day.

Further, it must be borne in mind that, outside of any question of wholesomeness, the water which a part of our people are content to use at present will not be considered suitable in a few years to come. The tendency is toward a general demand for a clear and colorless water, and water purveyors must be prepared to meet it.

Filtration of surface water, before delivering the same for public consumption, is now specifically ordered by the laws of Germany, and rules are laid down for its proper accomplishment. Such legislation is not improbable in this country, thus still further making it the part of wisdom to anticipate the artificial improvement of some waters which are now possibly considered beyond impeachment.

The method of purifying water on the large scale which deserves first attention on account of its early use and wide application is that of "slow sand filtration," commonly known also as

The English Filter-bed System.—Briefly described, an English filter bed is a tight reservoir, suitably underdrained, and containing some five or six feet of stratified filtering material, of progressive degrees of fineness, beginning at the bottom with broken stone or gravel, and ending with an upper layer of fine sand. Through the fine-sand layer the water slowly and evenly passes, leaving the bulk of its suspended impurities upon the surface to form the *Schmutzdecke*, or "dirt cover," of the Germans.

Beyond the mere gradual accumulation of suspended matter strained from the water, this *Schmutzdecke* is in part composed of slimy, jelly-like material, produced through bacterial agency, which serves to entangle and hold bacteria and other suspended substances of all kinds.

It must not be thought, however, that the extreme top layer of sand, with its cover of slime, does the entire work, so far as purification is concerned. Each grain of sand of the body of the bed becomes covered with a sticky coating of the zoöglœa jelly, and these grains collectively are to be credited with a large share of the results accomplished.

A filter recently disturbed by the process of cleaning is lower in efficiency than one which has been for some time in operation. Such a plant might be properly described as "at its best when at its dirtiest"; and, were it not that it finally becomes almost impervious to water, it would be better not to clean it at all. A new filter is of small use until it "ripens" for work; that is, until the "nitrifying" organisms have firmly established themselves and the zoöglœa jelly envelops the sand grains.

For proper working the thickness of the fine-sand layer should be made not less than thirty-six inches, and this depth should not be permitted greatly to decrease, by reason of the successive removals of layers of the upper surface for purposes of cleaning.

Usually filter plants are entirely open, but in those localities where the winters are severe it becomes necessary to throw over them a cover, which is commonly of concrete, resting upon columns of the same material. Thick ice renders it practically impossible properly to clean a filter by the ordinary methods, and the resulting imperfect purification of the filtrate is often coincident with increase in the death rate. This was noted in Berlin in the winter of 1889.

Hazen advocates the covering of filters in all localities where the mean January temperature is below the freezing-point.

The cost of constructing a filter bed must necessarily greatly vary, in direct ratio with the local cost of materials and with the difficulty of the engineering problem involved. Thus the open filters at Hamburg cost about $30,500 per acre, while the covered ones at Albany, N. Y., amounted to $45,600 for a like area.

The depths of water permitted upon filters of the English type are almost as various as the compositions of the beds themselves. Three and a half to four feet of water may be taken as the depth most commonly in use, and it is important that this depth, when once determined upon, should be maintained a constant.

With reference to the rate of filtration, the best practice places two and a half to three million United States gallons per acre per day, or four to four and a half vertical inches per hour, as the limit, beyond which the rate should not be pushed.

By direction of the imperial board of health, the maximum rate of filtration has been fixed in Germany at four vertical inches per hour.

For the purpose of cleaning a filter of the English type, a gang of laborers is set to work upon the drained bed, and by means of sharp shovels they pare off the upper half-inch of sand and pile the same into small heaps, whence it is removed by wheelbarrows to the sand washer. This thin upper layer of sand (the *Schmutzdecke* of the Germans) contains the greater bulk of the material separated from the water by filtration. It is quite compact, and is so distinctly separated from the sand below as to make the work of its removal very simple. It is liable to be quite membranous in character, and its imperviousness to water is what causes the filter to become "dead" and require cleaning.

The frequency with which filters have to be cleaned depends upon the condition of the water being filtered, and, for the same water, this condition will vary greatly with the time of year and character of the season. Roughly stated, it may be said that a filter becomes "dead" (*i.e.*, nearly impervious to water), and consequently demands cleaning, once every three or four weeks in summer and about half as frequently in winter; but it is not possible to lay down hard-and-fast general rules applicable to all filters. So many variable quantities enter the consideration that the question of proper time for scraping must be answered for each filter by itself, the final decision being based upon intelligent observation of the rate of flow, loss of head, and the obvious general efficiency. The average interval between scrapings at Albany is 25.1 days.

It is not customary nor desirable to have the newly ned filter remain out of service until the sand re- is washed and returned to its place; for the fine r should be thick enough to permit of a number of successive scrapings without impairment of its efficiency; therefore the sand taken off during a series of parings is all washed and returned at one time.

At Albany the sand layer, which is forty-eight inches thick, has been reduced as much as seventeen inches by successive parings before the normal thickness was restored by replacing the cleaned sand.

As to what may be expected from a sand filter in the way of bacterial removal, it may be said that during the year 1900 the Albany filters removed from 98.3 to 99.6 per cent. of all germs present in the raw water. Equally good results were accomplished by the beds at Altona, Germany, during the great outbreak of cholera at Hamburg in 1892. What such efficiency meant for the former city may be epitomized in the single word "safety."

It is not to be expected that municipal filtration plants will furnish the public with sterile water nor are we to look for perfect uniformity in bacterial efficiency, but it is a matter of fact that in those cities where modern filters have been established a very noteworthy reduction in the number of cases of typhoid fever has been observed. Thus in the city of Albany, where, previous to the introduction of filtered water, the average number of deaths from typhoid amounted to eighty-five per year, the influence of purified water is shown by a reduction of this number to less than twenty.

A modification of the English filter bed has been proposed, whereby filtration was to take place upward, and washing was to be done downward, the inlet for raw water and outlet for waste water being the same. By this arrangement the designer hoped to avoid all complications from ice, the ice cake being permitted to form freely and float clear of the sand bed. During washing a current of air was to have been let into the space underneath the bed, with a view to tumble the grains of sand and break up the sediment, so as to enable it to pass out with the wash water.

So far as principle is concerned, there may be little difference between upward and downward filtration, but in practice there would be serious objection to the former plan. Much difficulty would be experienced in securing uniformity of work over the whole area of the bed, owing to the impossibility of preventing the dirt layer falling off in spots, and it is well known that uniform action is of vital importance. It is moreover a dangerous practice to foul a filter in a place beyond reach of inspection and repair, for there is no way of determining whether or not the provided means of cleaning are working satisfactorily.

Mechanical Filtration.—Roughly outlined, this system consists in adding to the water to be filtered a minute dose of common alum or, better, aluminum sulphate, averaging nearly one grain per gallon, and then admitting the water to the filter, which is a tank of wood or iron, three-quarters full of uniformly fine sand. The carbonates present in the water decompose the alum, with the formation of a white flocculent precipitate of aluminum hydrate, quite jelly-like in appearance. For instance, the carbonate of calcium acts as follows:

$$Al_2(SO_4)_3 + 3CaCO_3 + 3H_2O = Al_2(OH)_6 + 3CaSO_4 + 3CO_2.$$

The action of this aluminum hydrate is much the same as that of the white of egg in clearing coffee. It entangles all suspended matter, germs as well as inorganic material, and deposits the same on the surface of the sand, whence it is removed and driven into the waste pipe by a reverse current of filtered water at the time of cleaning the filter. Thus, it will be observed, the mechanical filter produces an artificial inorganic jelly to replace the "bacterial jelly," already alluded to, of the English filter bed.

A further action of the precipitated aluminum hydrate is to unite with the soluble coloring matter of the water, whereby the filtrate is rendered colorless. The proper "dose" of alum solution is administered by means of some small automatic measuring apparatus exterior to the filter; the solution flowing thereto from the dissolving tank, where the coagulant is prepared in the proportion of twenty parts of water to one part of aluminum sulphate.

For small establishments it is a convenience to make use of a "closed" or "pressure" filter, for the reason that it can be placed directly upon the service main, thus allowing no interruption in the line of the supply. It is not easy, however, properly to watch such a filter, and it is open to sundry other objections, notably a lack of uniformity in action. For purposes of public use it is inferior to the open or "gravity" type.

The rate at which water is passed through these filters is very great when compared with what is furnished by the English filter beds already considered. One hundred and twenty-five million gallons per acre per twenty-four hours may be taken as a fair index of what is to be expected of them.

It has been already said that alum is used in their operation. The necessity for the use of this or some other coagulant is imperative and should be impressed upon the mind, for, however well the straining action of the sand bed may clarify the water, the great rapidity of flow precludes the proper removal of bacteria unless they be entangled in the alumina jelly noticed above.

Alum is by no means the only "coagulant" that could be or that has been used in mechanical filters. Salts of iron were suggested some years ago as a cheap substitute, but it is only recently that their use has been extended beyond the experimental stage.

What amount of coagulant should be used is a question best answered by the attendant in charge; for not only will the proper "dose" vary with different plants, but even in the same plant it may differ from day to day, and certainly will change from season to season. One grain per gallon is a fair estimate for a rough one.

It is worth remembering that theoretically a "dose" of one grain per gallon of aluminum sulphate (containing seventeen per cent. Al_2O_3) will require about eight parts per million of "alkalinity" in the water for its complete decomposition.

Danger to health from the use of alum is a topic fruitful of discussion among the many who are not posted as to its manner of action; but those who are better informed know that free alum never reaches the filtrate in a well-ordered plant.

Alum in the filtrate means a useless waste of material, not to be excused. Reference to the equation already given shows that in order to produce the aluminum hydrate jelly, upon which successful filtration depends, the alum admitted to the water must be entirely decomposed.

The method of testing for free alum is very simple, and the filter attendant, constantly on watch for it in the filtrate, should so manage the "dose" employed as never to allow it to pass beyond the sand bed.

The amount of filtered water used for the purpose of cleaning a mechanical plant is an item for consideration, for it is, of course, lost to the regular volume of supply.

At Rensselaer, N. Y., the average run between cleanings is about twenty-four hours, and the filters are washed with 3.75 per cent. of the filtered water. It takes eight minutes to wash each "unit" or separate filter.

One feature of mechanical filtration that has come into prominence of late is the addition of some form of settling tank. With certain waters it is essential that opportunity be given for sedimentation of a portion of the heavy magma produced by coagulation, otherwise the sand bed quickly chokes and the labor and expense of cleaning are greatly increased.

When the water is so soft as to be deficient in the necessary quantity of carbonates to decompose the alum added, the bed of ordinary filtering sand is sometimes replaced by a mixture of such sand and granulated marble, or else the water is hardened by passing it over broken limestone previous to the addition of the alum. A better plan is to add a suitable dose of "soda ash" to the raw water.

Should the water be highly colored as well as soft, the addition of alum should immediately follow that of the carbonate and a considerable interval should intervene before the filter sand is reached, in order to allow complete reaction and partial sedimentation to take place. The time element is of special importance in the purification of such waters, and is to be secured by the erection of large settling basins.

The cost of erecting a mechanical filter plant is somewhat difficult to give, for the reason that patent rights enter the estimate. Perhaps the fairest general statement that can be made is to place $10,000 per million gallons daily capacity as the basis price for a first-class plant, and to subtract from that sum such concessions as the special features of the case may be able to secure.

Filters can be erected for half the above amount, and they do good work for manufacturing purposes; but their bacterial efficiency is low and the water used for washing will be from eight to ten per cent. of the delivery instead of about three per cent., as found in the best forms of apparatus.

The question so frequently asked, as to which of the rival systems of filtration it is better generally to adopt, is not capable of a direct answer. Local conditions must first be known. Slow sand filtration is likely to be the better for very large cities, while for the supply of towns the mechanical system is commonly preferable.

Either method of filtration, to be of value, requires constant attention. Careful watch must of necessity be kept of a mechanical plant, however small, to secure its running at all, while very inefficient supervision is the usual fate of the small English sand bed. Once constructed, it is commonly left to look after itself until cleaning is imperative, and then laborers are put upon the work who have never seen its kind before.

It is very doubtful policy to build an English sand bed unless the plant be large enough to maintain a skilled force constantly employed. It may be further generally said that, although relatively expensive for small plants, the English system rapidly lessens in cost, per unit of capacity, as the plant increases in size. This decrease is not so rapid for mechanical filters.

Other things being equal, English plants are perhaps better suited for clear waters, and mechanical filters for those of turbid or colored character.

The life of an English filter is practically unlimited, while that of the mechanical type is as yet undetermined.

Finally, it is an easier and cheaper matter to keep the mechanical filter nearer the present requirements as to capacity and to add to it by small extensions as circumstances may exact. So far as bacterial efficiency is concerned, either type will satisfactorily meet the demands.

Experiments of extended and costly character have been made with a view of securing data whereon to base a decision as to the merits of rival systems of filtration, and it is quite reasonable that the question should be asked, Why is it necessary to multiply such tests? Why cannot Louisville and Pittsburg results be made to do service elsewhere? To a large degree such use is possible, but it must be remembered that waters differ from one another more widely than the bulk of people appreciate. Thus the mere item of suspended matter is a case in point. Not only does the amount thereof greatly vary, but the character of the material causing the turbidity, and especially its degree of fineness, should command especial attention. Two equally turbid waters may look alike to the eye, but the fine suspended matter of one may be easily arrested by an English sand bed, while the other may give a filtrate of decided opalescence. Hence the demand for local experiments in important cases.

Nearly akin to the filter plants referred to above is a group of appliances among which the "Anderson process" is perhaps the best known. In this process the water is forced through purifiers consisting of iron cylinders revolving on hollow trunnions which serve for inlet and outlet pipes. On the inner surface of the cylinders are curved ledges running lengthwise, which scoop up iron borings or punchings and shower them down through the water as it flows through the cylinder. Iron passes into solution and is afterward rendered insoluble by exposing the water to the atmosphere. By filtration through sand this iron precipitate is subsequently removed, together with what suspended matter it may have entangled.

Excellent results are secured by the Anderson process, but an additional and expensive step is introduced in the item of revolving machinery, before the water is run upon the sand filters; and it is not proved that this further outlay of capital is necessary, in view of the cheapness of some of the other and simpler methods.

Household filtration on the domestic scale is in very general operation, yet satisfactory results are obtained in an exceedingly small percentage of cases.

The companies manufacturing the mechanical filters previously mentioned all make sizes intended for domestic use, but the skilled labor furnished by a city employee whose sole duty it is to attend to the public plant is very rarely obtainable in the average household; consequently the filter is neglected or mismanaged, or both. In short, filtration, to be effectual, should be municipal. A house filter that has come widely into use, and upon which very many people pin their faith, is the well-known "Pasteur." It is commonly operated under the pressure of the city mains, but may also be arranged to work without additional pressure beyond that of the atmosphere. For those unacquainted with its use, it may be said that it consists of a cylinder of fine unglazed porcelain (called "candle," on account of its size and shape) enclosed by one of metal; and that, connection having been established between the latter and the supply pipe, the water is forced through the pores of the porcelain to the inside of the cylinder (the so-called candle), whence it drops into the reservoir, leaving the suspended matter as a coating upon the "candle's" exterior surface. (Fig. 5035.)

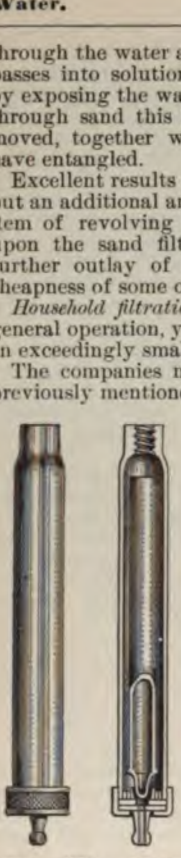

FIG. 5035. — Pasteur-Chamberland Filter.

Examination of the efficiency of the Pasteur filter has been thoroughly done by a number of investigators, with results that may be summarized as follows: Water can be completely sterilized by filtration through porcelain, but the filtration must not be continued for many days at a time. The length of time during which a sterile filtrate may be obtained will depend upon the temperature of the filter and its contents. Thus, according to Freudenreich, at a temperature of 59° to 64° F. the filtrate was sterile for from fifteen to twenty-one days, at a temperature of 72° F. it was sterile during nine days, while at a temperature of 95° F. it remained sterile only five days.

Water pressure is not a factor in causing germs to pass through the porcelain, for their method of penetration is one of development rather than a transporting of initial bacteria; in other words, they "grow" through the filter. Even when the pressure is nil they accomplish the passage in the usual length of time. This power of growing through the pores of the porcelain has been denied by a recent observer, but it is on the side of safety to hold to the earlier records.

From a consideration of these facts the line of management for a "Pasteur" becomes plainly evident. The "candle" and its rubber packing must be removed at least once a week, thoroughly washed, and then boiled for half an hour before being reset in position.

Especial care should be taken that the rubber packing make a tight fit, as otherwise the water may pass around rather than through the porcelain. The filter should not be located in too warm a place.

The lateral connecting the filter with the supply main should be of tin or iron, as the slow action of the filter allows the water to remain for a considerable time in contact with the metal.

Many types of household filters are of such character as to preclude the possibility of sterilization, and some of them it is even impossible to clean without the entire renewal of the filtering material. Such defects are necessarily fatal to proper filtration. The stone filters one sees at times, where the water is caused to drip through fine-grained sand rock, or similar material, act as mere strainers and are absolutely unreliable. Currier demonstrated that sponge filters, after use for even a single day, furnished a filtrate containing five hundred times as many germs as the unfiltered water. Household filters of many types are to be seen so seriously contaminated that a water cannot but be rendered worse by passage through them, and yet such appliances are in full use and greatly trusted on account of the apparent clearness of the water drawn from them.

Much stress is often laid upon the purifying effects of animal charcoal, and the great quantity of occluded oxygen the fresh charcoal contains fully justifies for a time the high praise given it, but such material is nearly impossible to cleanse, and it has been repeatedly shown that a more objectionable appliance could scarcely be found, from a sanitary point of view, than a neglected charcoal filter.

Aeration of water has always held in the public mind a position of prime importance as a means of purification. There is unquestioned benefit arising from the passage of water over falls and rapids, and from its being thrown into the air in fountains, but the benefit is not so great as is commonly believed.

Such treatment tends to prevent the abundant growth of algæ, with their objectionable tastes and smells, and undoubted improvement in the quality of the water results from the establishing of a fountain in, or otherwise blowing air into, a too quiet reservoir; but the expectations of those who hope thus easily to eliminate pollution of a more serious character will not be realized.

Aeration is of especial value in rendering some kinds of ferruginous well waters, which are otherwise pure, fit for domestic use. The iron is thereby oxidized to insoluble ferric oxide, and may be easily removed by filtration.

In these days of "applied electricity," it would be strange indeed if attempts were not made to harness up the "fluid" for the work of water purification, as an addition to the many other tasks already assigned to it.

One movement toward such an end consists in decomposing a weak solution of common salt by means of a current from a dynamo, and then adding the electrolyzed liquid to the water to be purified, in the proportion of about 10 grains per gallon of water or 1 part to 5,833 by weight.

The product of the electrolysis is fancifully styled "electrozone," but the germicidal power which it possesses is due to the well-known sodium hypochlorite formed during electrolysis, and not to the presence of ozone.

The sodium hypochlorite prepared by this method is not different from that made in the ordinary way, and in germicidal power it is equalled by an equivalent weight of the calcium salt, called "bleaching powder," the efficiency of each being measured by the amount of available chlorine present.

The insoluble salts resulting from the employment of "bleaching powder" would, however, be a disadvantage in its use unless opportunity were afforded for settlement, and, moreover, it would render the water harder.

To "disinfect" a water by the use of hypochlorites does not appeal to one as a suitable means for increasing its potability.

The actual application of ozone in the form of ozonized air to the purification of water has a number of earnest supporters, and we await with interest the further development of such a process. Up to the present, however, it is right to say that the experimental stage is scarcely passed, although the flattering results secured by experiments permit us to entertain expectations of ultimate success.

From a sanitary standpoint, the method for purification of water which excels all others in efficiency is distillation. The peculiar taste of freshly distilled water is, however, disagreeable to many, and for that reason the process is not likely to become speedily popular, even if the expense be not too great.

It would seem that the attention of the public has been largely drawn of late to the question of the wholesomeness of distilled water for dietetic purposes, numerous articles having issued from the press under such captions as "Poisonously Pure Water" and the like. Much uneasiness has been created among those who have used such water, because of their being told that "distilled water is an active protoplasmic poison, due to its property of extracting salts from animal tissues and causing them to swell up by imbibition." Stress is, of course, laid upon the increased danger arising from its use by the young, whose tissues are in process of formation.

In consideration of the mixed character of human food and the amount of mineral salts naturally occurring therein and added thereto as condiments, the withdrawal of two or three grains of-such salts per day, by the substitution of distilled water for that drawn from some natural source, would be a matter of too small importance for consideration.

Distilled water is used for drinking purposes on practically every vessel in the United States navy, and the surgeon-general says: "It may be stated that the medical officers of the navy recognize the great value of distilled water in the improvement in health that has followed its introduction, particularly on certain foreign stations."

The good old household remedy of boiling a suspicious water is always available, but unfortunately it is but seldom applied. As an illustration of its value it is worth noting that during the cholera outbreak at Lucknow, among the members of the East Lancashire Regiment, there was no cholera whatever in company E. This company was the only one which boiled the drinking-water.

Finally, let it be noted that there is no way of purifying a polluted water, as some people would have us do, by throwing a remedy into the well or cistern.

WATER ANALYSIS.—A great deal of popular misconception exists upon the subject of the analysis of potable water, and it is commonly supposed that such an examination may be looked upon from practically the same point of view as the analysis of an iron ore. In point of fact, however, it is a very different matter.

A water analysis is really not an analysis at all, properly so called, but is a series of experiments undertaken with a view to assist the judgment in determining the potability of the supply. Some of the substances reported, "albuminoid ammonia," for instance, do not exist ready formed in the water at all, and are but the experimental measures of the objectionable organic constituents, which our present lack of knowledge prevents our estimating directly.

It is not practicable to furnish the public with the means of fully understanding the numerical results as stated, nor is it possible to supply general "standards of purity" whereby a water may be rated as wholesome or otherwise, for the reason that figures which would condemn a water in one locality might be entirely without objection for a water derived from a neighboring county.

The examiner must be in full possession of all the facts concerning the water which he is asked to test, in order that his opinion as to its purity may be based upon the entire breadth of his past experience, for in no branch of analytical work are experience and good judgment better exercised than in the interpretation of a water analysis.

It is a great mistake to suppose that the proper way to consult a water expert is to send a sample of the water in a sealed vessel with no hint as to its source. On the contrary, he should be thoroughly acquainted with the history and source of the water and, if possible, he should take the samples himself. For so important a matter as a town supply, he should unquestionably personally superintend their collection.

Finally, let it be said that a water analysis is, for purposes of economy, rarely made complete. For ordinary drinking-water the question is always asked, "is it wholesome?" To answer this, the analysis of the mineral residue left upon evaporation is not usually required, so that much time and expense may be saved by simply reporting this as "total solids." On the other hand, analyses of mineral waters deal with this feature of the examination very largely, and usually to the exclusion of those portions, such as "albuminoid ammonia," "required oxygen," etc., which are important in the "sanitary analysis." The same may be said of the analyses of waters for boiler use.

Large glass-stoppered bottles are best for sampling. After thorough rinsing with the water to be analyzed, fill the vessel to overflowing so as to displace the air, and then completely empty it.

If the water is to be taken from a tap, let enough run to waste to empty the local lateral before sampling; if from a pump, pump enough to empty all the pump connections; if from a stream or lake, take the sample well out from the shore, and sink the stoppered sampling vessel toward mid-depth before removing the stopper, so as to avoid both surface scum and bottom mud. In every case fill the vessel nearly full, leaving but a small space to allow for possible expansion, and close securely. Under no circumstances place sealing wax upon the stopper, but tie a piece of cloth firmly over the neck to hold the stopper in place. The ends of the string may be afterward sealed if necessary. Having secured the sample, the analysis should be begun at once, for the reason that water is liable to rapid changes in character during laboratory storage.

The results of the chemical examination should be stated in "parts per million" in weight. Water should not be filtered before analysis. If sediment be present, it should be equally diffused by thorough shaking before measuring. The reason for this is that a water analysis should represent the water as the consumer uses it, and not in a condition improved by filtration.

The analysis cannot be properly conducted in a general laboratory, because many of the tests would be ruined by the fumes common to such a locality. A separate room, reserved exclusively for water work, is the best arrangement.

The appearance and turbidity of a water are best determined by using a brass tube two and one-half inches in diameter and two feet long, closed at the ends by discs of quarter-inch plate glass held in place by screw caps.

For the purpose of measuring the amount of turbidity, a standard is prepared, consisting of 1 gm. of exceedingly fine kaolin (obtained by elutriation) suspended in one litre of distilled water. Each cubic centimetre of this preparation will contain 1 mgm. of suspended clay. Having nearly filled the duplicate observation tube with distilled water, enough of the "clay standard" is added to make the "turbidity" equal to that of the water under examination in the other tube. Knowing the volume of water operated upon and the amount of "clay standard" used, the "turbidity" expressed in parts per million can readily be calculated. For more rapid although less accurate observations, the tubes above mentioned may be replaced by a number of half-gallon bottles, in which a series of turbidity standards are kept ready for immediate use.

As used by the United States Geological Survey, the turbidity standard is a suspension of silica (infusorial earth) of such a fineness that a bright platinum wire 1 mm. in diameter can just be seen when the centre of the wire is 100 mm. below the surface of water which contains in suspension one hundred parts of such silica per million parts of water. The turbidity of such standard is rated as 100.

A turbidity rod with graduations based upon this standard is prepared for the survey and is very convenient for use in the field.

When variations in turbidity are being watched in a locality where the suspended matter is colored, the "clay standards" should be prepared from local material.

The reaction of natural water is commonly slightly alkaline, although waters holding much free acid in solution, usually sulphuric, are by no means rare.

Determination.—Place 100 c.c. of the water in a casserole, and titrate with N/10 hydrochloric acid, using methyl orange as an indicator. Should the water be originally acid, make it slightly alkaline with a known amount of potassic hydrate before titration. It is convenient to report alkalinity as representing so many parts of $CaCO_3$ per million of water, and to note that such a form of result corresponds to fifty times the number of cubic centimetres of hydrochloric acid, used in the titration.

Acidity is best stated in the same terms using a negative sign.

Color.—Dissolve 1,246 gm. potassic platinic chloride and 1 gm. cobalt chloride in 100 c.c. strong HCl and dilute with distilled water to 1 litre. This solution has a color of 500.

By placing one, two, three, four, etc., cubic centimetres of such solution in 50 c.c. "Nessler" jars and diluting to the mark with distilled water, standard colors of 10., 20., 30., 40., etc., are obtained, and with these is compared a 50 c.c. "Nessler" jar filled with the water under examination. Turbid waters should be filtered before reading the color.

Total Solids.—Material dissolved or suspended in water is naturally derived from the strata through which the water passes or the surface over which it flows. Thus are obtained waters of all degrees of hardness and of great variety of color and turbidity.

Determination.—Thoroughly shake the vessel containing the sample and then measure out 100 c.c. of the unfiltered water by means of a pipette into a weighed platinum dish. Evaporate to dryness on the water bath, being careful to place a filter paper between the dish and the water in the bath in order to prevent any deposit of impurities on the under side of the dish. (A better plan is to make use of a porcelain water bath filled with distilled water.) When dry, place the dish and contents in an air bath and maintain the temperature at 105° C. for half an hour. Cool in a desiccator and weigh.

Comparates.—Average in sundry surface waters known to be pure, 74; known to be polluted, 194; average in sundry ground waters known to be pure, 144; known to be polluted, 642.

These averages are really of but small sanitary value, for the reason that a polluted water may be low in total solids, or *vice versa*, according to the character of the soil through or over which the water flows.

HARDNESS.—Before entering into the question of quantitative estimation, let it be premised here that "hardness" may be classified under two heads, viz., "Permanent" and "Temporary." The former is occasioned by the presence of calcium sulphate and other soluble salts of calcium and magnesium, not carbonates, held in solution by the solvent action of the water itself; such a water cannot be materially softened by boiling under ordinary pressure.

"Temporary" hardness is caused by carbonates of calcium and magnesium held in solution by carbonic acid present in the water. Boiling such a water expels the carbonic acid, whereupon the salts separate from solution.

Hehner's method for determining "permanent hardness" is very convenient: The measured water is boiled down with a known excess of Na_2CO_3. Precipitated $CaCO_3$ is filtered off, and the remaining Na_2CO_3 determined by titration with standard acid and methyl orange. The loss in Na_2CO_3 is calculated to a corresponding amount of $CaSO_4$.

"Temporary hardness" is usually equal to the "alkalinity," previously determined.

Should sodium or potassium carbonates be present, the acid required to neutralize the water residue, after boiling down as above, will be greater than the amount corresponding to all of the standard Na_2CO_3 solution added, for no permanent hardness could be present in such a case. From such excess of acid the carbonates of the alkali metals can be calculated. Their equivalent in terms of $CaCO_3$ should be subtracted from the total "alkalinity" in order to state correctly the "temporary hardness."

Comparates.—The average hardness of good waters as given by the British Rivers Pollution Commission stands: Rain, 3; upland surface, 54; deep well, 250; spring, 185.

Chlorine.—Water is rarely found free from chlorine, yet, notwithstanding its almost constant presence, there is hardly a factor in the sum total of water analysis toward which attention is more quickly turned or regarding which there is closer scrutiny.

In most instances chlorine is present in the form of common salt, washed from the air or soil, or added as one of the constituents of sewage. Salt itself is, of course, unobjectionable in the quantity usually present, but, it being so largely used in our food, there is always warrant for suspecting sewage contamination where the figures for chlorine run high.

True it is that those figures are at times misleading, but they, like other data in water analysis, must be considered with judgment, and due weight be accorded the character of local surroundings.

If the district whence the water comes be naturally rich in salt, as is the case with the deep-seated waters of Central New York, such fact must be borne in mind when formulating an opinion as to quality. Variation in the chlorine contents of rain water always occurs inland, although not to the same degree as upon the coast. Ground water is more directly influenced than rain water by the presence of human habitation.

The determination of chlorine in water is extremely simple. It depends upon the fact that if to a solution of a chloride which has been colored yellow by addition of a little potassic chromate a solution of silver nitrate be added, white silver chloride will be produced until the last trace of chlorine shall have been disposed of, whereupon red silver chromate will begin to appear.

The reagents required are:

Standard Silver Solution.—Prepared by dissolving 4.8022 gm. of crystallized silver nitrate in 1 litre of water. Each cubic centimetre of such a solution is of a strength sufficient to precipitate 1 mgm. of chlorine.

Potassium Chromate, Indicator.—Dissolve 2 gm. of the pure salt in 100 c.c. of distilled water.

Sodium Carbonate Solution.—Dissolve 50 gm. of the pure salt in 300 c.c. of distilled water.

Determination.—One hundred cubic centimetres of the water to be examined are placed in a large "Nessler" jar; 1 c.c. of the potassic chromate solution is added, which will give a distinct yellow color, and then the standard silver solution is run in from a burette until the red tint of the silver chromate just appears. From the known amount of silver solution used the amount of chlorine present is obtained, and this, multiplied by ten, will give the chlorine in milligrams per litre or parts per million.

To determine with accuracy the first appearance of the red tint, it is best to make the examination in yellow light, either by the use of a photographic "dark-room" lantern with a front of yellow glass or by simply looking through a plate of such glass. Reflection from a porcelain tile throws the light through the length of the "Nessler" jar, and side light is cut off by a black screen.

For the sake of accuracy it is better, during the titration, to have a second jar of the water, also colored with potassic chromate, in order that the formation of the red tint in the vessel operated upon may be, by contrast, more readily detected.

Many waters possess such deep color or such turbidity as to interfere with proper titration; under such circumstances it is best to shake the water with recently precipitated and washed aluminum hydrate and then filter it, or allow it to stand twenty-four hours in a tall glass cylinder. The coloring matter or turbidity is thus sedimented and the water cleared for use.

Comparates.—Average in sundry surface waters known to be pure, 3.57; known to be polluted, 6.06; average in sundry ground waters known to be pure, 3.2; known to be polluted, 91.7.

NITRITES.—Whether the presence of nitrites be considered due to reduction of pre-existing nitrates in the presence of organic matter or caused by direct oxidation of organic nitrogen, it becomes a necessity to estimate their quantity, for in either case the initial cause is probably contamination.

Of the several methods used of late for the determination of nitrites, the second one suggested by Griess seems to be the most deserving of favor. It depends in principle upon the red coloration ("azobenzolnaphthylamine sulphonic acid") produced whenever "sulphanilic acid" and "naphthylamine hydrochloride" are added to an acidified solution of nitrite. The test is exceedingly delicate and is capable of distinguishing one part of nitrogen as nitrous acid in one thousand million parts of water.

The reagents are prepared as follows:

Sulphanilic Acid.—Dissolve 1 gm. of the salt in 100 c.c. hot water. The solution keeps well.

Naphthylamine Hydrochloride.—Boil 0.5 gm. of the salt with 100 c.c. water for ten minutes, keeping volume constant. Place in glass-stoppered bottle. The solution tends to grow slightly pink on standing, but not sufficiently so to interfere with its use.

Standard Solution of Sodium Nitrite.—Sodium nitrite may be bought, but its purity is always to be questioned, and, moreover, it is too deliquescent a salt to be weighed with ease and accuracy. It is better, therefore, to prepare the silver salt, which may be readily handled, and from it the solution required may be made.

To a cold solution of commercial sodium or potassium nitrite add a solution of silver nitrate as long as a precipitate appears. Decant the liquid and thoroughly wash the precipitate with cold water. Dissolve in boiling water. Concentrate and crystallize the silver nitrite from the hot solution. Dry in the dark at the ordinary temperature (using vacuum is better) and keep it in a black bottle.

Weigh out 0.22 gm. of the dry silver nitrite. Dissolve in hot water. Decompose with slight excess of sodium chloride, cool if necessary, and dilute to 1 litre. Allow the precipitated silver chloride to settle, remove 5 c.c. of the clear solution, and dilute the same to 1 litre. This second dilution (which is the standard solution to be used) will contain an amount of nitrite per cubic centimetre equivalent to 0.0001 mgm. of nitrogen.

Determination.—Place 100 c.c. of the water to be examined in a "Nessler" jar. Acidify with one drop concentrated HCl. Add 1 c.c. of the sulphanilic-acid solution, followed by 1 c.c. of the solution of hydrochloride of naphthylamine, mix, cover with watch glass, and set aside for thirty minutes. Prepare at the same time other "Nessler" jars containing known amounts of the standard solution of sodic nitrite and diluted to the 100-c.c. mark with *pure* distilled water, adding the reagents as above. At the end of the time stated (thirty minutes) examine the depth of the pink color formed, and by comparing the unknown with the known an accurate determination of the amount of nitrogen present as nitrites may be made.

If much gas be burning in the room, nitrites will be in the atmosphere. Hence cover the jars or remove them from the room during the half-hour interval before reading.

Nitrites are sometimes found in deep-well waters of good quality, but in ground or surface waters their presence should be always regarded with suspicion.

Comparates.—Average in sundry surface waters known to be pure, 0.000; known to be polluted, 0.006; average in sundry ground waters known to be pure, 0.000; known to be polluted, 0.003.

NITRATES.—Nitrates present in water are but the further step in the oxidation of nitrogenous organic matter. They are more liable to indicate putrefaction of animal rather than of vegetable tissue, not only because of the greater quantity of nitrogen present in the former, but also on account of its more ready decomposition.

Rain water washes a very considerable amount of nitric nitrogen from the air, while in the soil the atmospheric nitrogen is fixed through the agency of the roots of certain plants, such as peas, the process being aided by bacterial action.

Such fixed nitrogen eventually enters the ground water, and a knowledge of the local "normal" for nitric nitrogen is consequently of advantage when studying the domestic well waters of a neighborhood.

Surface and ground waters of good quality are low in nitrates, for the reason that such material is quickly absorbed by growing vegetation, but waters from deep wells often give large figures for that item.

When phenolsulphonic acid is brought in contact with a nitrate, and ammonia is afterward added to alkaline reaction, yellow ammonium picrate is formed.

The intensity of this yellow color, produced in the water under examination, is compared with colors of known strength, and the quantity of nitrate present thus determined.

The interference of chlorides with this process results in readings lower than the truth, but if the chlorine be below ten parts per million such interference is not material.

The solutions required are:

Phenolsulphonic Acid.—Sulphuric acid, pure and concentrated, 148 c.c.; distilled water, 12 c.c.; pure phenol, 24 gm.

Standard Potassium Nitrate Solution.—Dissolve 0.7221 gm. pure KNO_3 in 1 litre distilled water. This solution contains 0.1 mgm. of nitrogen as nitrate in each cubic centimetre.

Determination.—Evaporate 100 c.c. (or less, according to nitrate contents) of the water to dryness on the water bath, having previously added a few drops of sodium carbonate solution to prevent loss from volatilization of nitric acid. Thoroughly moisten the residue with 2 c.c. of the sulphonic acid. Add an excess of ammonium hydrate. Make up to 100 c.c. in a "Nessler" jar, and compare the depth of color with those produced by operating upon different amounts of the standard nitrate solution, which have been evaporated and treated under precisely similar conditions.

In order to economize time, when dealing with waters low in chlorine, it is convenient to use a standard "nitrate color solution." This is made by evaporating 25 c.c. of the standard potassium nitrate solution, followed by addition of the other reagents in the way already detailed.

The yellow liquid produced is diluted to 1 litre and kept in stock. Each cubic centimetre thereof corresponds to 0.0025 mgm. nitrogen as nitrate. Much time is saved by diluting measured volumes of this "standard color" to 100 c.c. for the preparation of the comparison tubes.

The solution keeps its normal strength of color quite well, but should not be trusted after having been a few weeks in stock.

Before evaporating for the nitrate determination it is best to clear the water with aluminum hydrate as under "chlorine."

Comparates.—Average in sundry surface waters known to be pure, 0.139; known to be polluted, 0.749; average in sundry ground waters known to be pure, 1.4; known to be polluted, 11.9.

Mallet found in thirteen samples of water "known to be pure" the nitrogen present as nitrates averaged 0.42 (the extreme limits being 0 and 1.04), while in twenty samples of water believed to be objectionable the average figures ran 7.239 (the extreme limits being 0 and 28.403).

Organic Matter.—It is here that water examination loses its analytical features and becomes experimental in character. Organic matter cannot be determined directly and we are forced to resort to certain lines of procedure which experience has taught us differentiate more or less sharply between good and bad waters, even though the actual composition of such waters be not thereby revealed.

Organic matter containing nitrogen, when breaking down through putrefaction, liberates its nitrogen as ammonia, and this in turn changes to nitrites and nitrates of the bases present. The ammonia formed, as above, may be separated from the water by simple distillation and when determined is reported as "free ammonia." Such of the nitrogenous organic matter as yet remains undecomposed may be in great part broken up, and its nitrogen given off as ammonia, by distillation with strongly alkaline potassium permanganate. This second evolution of ammonia is called "albuminoid," for the reason that albumin acts in like manner when similarly treated. Wanklyn's "albuminoid ammonia process" is based upon the foregoing facts.

The reagents necessary are:

"*Nessler's*" *Solution.*—Dissolve 16 gm. mercuric chloride ($HgCl_2$) in about half a litre of pure water. Dissolve 35 gm. potassic iodide (KI) in about 200 c.c. pure water. Pour the first solution into the second until a faint show of excess is indicated. Add 160 gm. solid potassium hydrate (KOH). Dilute to 1 litre, and finally add strong solution of mercuric chloride, little by little, until the red mercuric iodide just begins to be permanent. Do not filter from excess of mercuric iodide, but let the same settle to the bottom of the vessel. The finished reagent should have a pale straw color. It is improved by age.

"Nessler's" solution will give a distinct brownish-yellow coloration with the most minute traces of ammonia or ammonium salts. If the quantity of ammonia be at all considerable, a brown precipitate will appear.

Pure Water.—This must be prepared with great care, in a room free from the usual laboratory fumes. In short, the entire examination of potable water should be undertaken in a locality other than a general working laboratory. The most suitable retort for this purpose is of copper, three gallons in size, and with a tin condensing worm. Fill it with good spring water, distil, collect distillate in 50-c.c. "Nessler" jars, and to each successive jarful so collected add 2 c.c. "Nessler" solution. After waiting five minutes, should a brown tint be observed upon looking through the liquid (*longitudinally*) at a white porcelain tile or piece of white paper, the presence of ammonia is indicated.

Continue the distillation and the "nesslerizing" of the successive 50-c.c. portions of the distillate until no coloration is obtained even after standing for five minutes. When ammonia ceases to be detected, the distilled water may be collected for use. The distillation should not be pushed too far, both on account of danger to the retort and of possible production of ammonia from decomposition of the organic material remaining in the bottom.

Alkaline Potassic Permanganate.—Dissolve 200 gm. solid potassic hydrate and 8 gm. crystallized potassic permanganate in 1,250 c.c. of pure water. Boil down to 1 litre and keep for use.

Sodic Carbonate Solution.—Dissolve 50 gm. of the pure salt in 300 c.c. pure water.

Standard Ammonia Solution.—Dissolve 1.5706 gm. of pure dry ammonium chloride in half a litre *pure* water. Dilute 5 c.c. of this solution to half a litre with *pure* water. This second solution will represent a strength of 0.01 mgm. of NH_3 per cubic centimetre, and is the standard solution used.

DETERMINATION OF FREE AMMONIA.—Fit a one-quart glass tubulated retort to a large Liebig condenser, letting the neck of the retort pass well into the condensing tube and through a large-size soft-rubber stopper. This connection must be thoroughly tight. Place 250 c.c. *pure* water in the retort and add 10 c.c. of the sodic carbonate solution. Distil off three 50-c.c. jars of water, and "nesslerize" the third in order to be sure that no ammonia yet remains in the retort. Any ammonia that may have resulted from the imperfect cleaning of the apparatus, or that may have been present in the sodic carbonate solution, will usually all go over in the first 50 c.c. of distillate, but the same quantity (*i.e.*, 150 c.c.) must be distilled off in all cases in order that when the actual analysis of the unknown water is started upon the condition as to volume may be constant.

In fact, it may be conveniently stated here that *perfect uniformity of conditions* is a requisite for success in water analysis.

To the contents of the retort is now added half a litre of the water to be examined.

Distil and catch the distillate in 50-c.c. "Nessler" jars. The rate of the distillation should be so managed as to allow about fifteen minutes for the filling of each 50-c.c. jar. Add 2 c.c. "Nessler" reagent to each jarful, and continue the operation with each successive portion of the distillate until no further reaction for ammonia is apparent after waiting five minutes. Usually four jars will be sufficient to carry off all free ammonia, but it is customary to distil off six.

From a small burette measure definite amounts of the *standard ammonia solution* into several clean "Nessler" jars. Dilute each to the 50-c.c. mark with pure water, add 2 c.c. "Nessler" solution, and after standing for five minutes compare as to depth of tint with the distillates already "nesslerized." With a little practice it will be found easy, by varying the amounts of standard ammonia solution used, to produce tints corresponding to those existing in the distillates, and thereby a most accurate knowledge of the quantity of ammonia actually present may be obtained. Such ammonia existed ready formed in the water, either free or as an ammonium salt, and passed over unchanged with the steam; it is therefore technically known as "*free ammonia.*"

To make clear the calculation of results let us cite an example: Suppose the first jarful to have required 9 c.c. standard ammonia solution (diluted to 50 c.c.) to match its color when "nesslerized," the second one 3 c.c., and the third 1 c.c. Then, since each cubic centimetre of the standard ammonia solution corresponds to 0.01 mgm. NH_3, the whole amount of "free ammonia" present in the original half-litre of water would be: First, 0.09 mgm.; second, 0.03 mgm.; third, 0.01 mgm.; fourth, 0.00 mgm.—total, 0.13 mgm. Multiplying this by two to obtain the quantity for an entire litre, and remembering that 1 mgm. is the millionth part by weight of a litre of water, we find the total "free ammonia" present in the water to be 0.26 *part per million.*

ALBUMINOID AMMONIA.—Throw out the residue remaining after the distillation for *free ammonia*, clean the retort thoroughly, and refit it to the condenser. Place in the retort 200 c.c. pure water and 50 c.c. of the *alkaline permanganate solution.* Distil off three 50-c.c. jars and "nesslerize" the third one in order to insure freedom from ammonia. Add half a litre of the water under examination, and proceed with the distillation and the "nesslerizing" of the successive 50 c.c. portions of the distillate, as in the determination of *free ammonia.* The distillation is to be continued until six 50-c.c. jars are filled. The ammonia determined by this distillation will be *total* (*i.e.*, "free" plus "albuminoid"); therefore from the Nessler reading of each jarful of distillate must be subtracted the reading for the corresponding jarful for "free ammonia": the difference will give the "albuminoid ammonia" for that jar.

The calculation is entirely similar to that for *free ammonia*, as stated.

Concerning the interpretation of results, Wanklyn is very dogmatic, and says: "The analytical characters, as brought out by the ammonia process, are very distinctive of good and bad waters, and are quite unmistakable." This statement is altogether too strong. Waters of high organic purity or those of gross pollution are undoubtedly easy to classify, but with the numerous cases which lie about the boundary line between "good" and "bad," the greatest care is to be exercised in the reading of results and the passing of judgment.

As an illustration of variation in the ammonias, the following data are offered:

	Free ammonia.	Albuminoid ammonia.
Average in sundry surface waters known to be pure	0.063	0.066
Average in sundry surface waters known to be polluted	.182	.228
Average in sundry ground waters known to be pure	.009	.007
Average in sundry ground waters known to be polluted	.107	.081

The "free ammonia" in artesian wells is often excessive, under circumstances that make animal contamination an impossibility, and even rain water, freshly collected after periods of long drought, will often exhibit properties calculated to mislead the analyst.

Free ammonia is at times very high in the rain water collected near large cities, and is liable to run higher in winter than in summer. Of course high figures under such conditions are without objection, assuming a clean roof and a clean cistern; but when dealing with a rain water it must be always borne in mind that storage cisterns are often very foul.

As a further aid to judgment the following analyses are given of sundry waters in different parts of the country, several of them having caused disease. Also a few instances of waters of reliable quality.

The solution tends to grow weaker quite rapidly with lapse of time, and must be restandardized every time it is used. This is, however, but a slight inconvenience, and is accomplished as follows:

Ten cubic centimetres of the oxalic-acid solution, diluted with 200 c.c. pure water and 10 c.c. of the dilute sulphuric acid, are titrated, boiling, with the standard potassic permanganate solution, and the amount of the latter required to produce a faint pink tinge is recorded.

Determination.—Place in a porcelain casserole 200 c.c. of the water under examination, and add 10 c.c. of the dilute sulphuric acid. Heat rapidly to incipient boiling, and run in the standard permanganate solution from a burette until the water has a very marked red color. Boil *ten minutes*, adding more permanganate from the burette from time to time, if necessary, in order to maintain the intensity of red color observed at the start. Do not let the color fade nearly out, and then add the permanganate in quantity at once, but strive to keep the color as nearly constant as possible by gradual addition.

Remove the lamp, add 10 c.c. (or more, if necessary) of the oxalic-acid solution to destroy the color, and then add the permanganate solution from the burette until a faint pink tinge again appears. From the total permanganate used deduct that corresponding to the 10 c.c. (or more) oxalic acid employed, and from the remainder calculate the milligrams of "required oxygen" consumed by the organic matter present in the water. Correction must be made for nitrites, ferrous salts, or hydrogen sulphide if any of them be present.

No.		Free ammonia.	Albuminoid ammonia.	Chlorine.	N as nitrate.	N as nitrite.	Required oxygen.	Total solids.

OXYGEN-CONSUMING CAPACITY ("Required Oxygen").—This method for estimation of organic matter is Kubel's modification of the old permanganate process of Forschammer. The necessary solutions are.

Standard Potassic Permanganate Solution.—Dissolve 0.3952 gm. of the salt in 1 litre of distilled water Each cubic centimetre of such solution will contain 0.1 mgm. of oxygen available for oxidation. The available oxygen of the permanganate in presence of sulphuric acid may be represented by the equation

$$K_2Mn_2O_8 + 3H_2SO_4 = K_2SO_4 + 2MnSO_4 + 3HO_2 + 5O.$$

Dilute Sulphuric Acid.—One part of the strong acid to three of distilled water.

Solution of Oxalic Acid ($H_2C_2O_4.2H_2O$).—Dissolve 0.7875 gm. of the crystallized acid in 1 litre of distilled water. This solution if titrated against the permanganate solution (while hot, and in presence of H_2SO_4) should correspond to it cubic centimetre for cubic centimetre. In practice, however, this correspondence will be found to be approximate only.

Example:

Total permanganate solution used	25.0 c.c.
Less that required for the oxalic acid	9.7 c.c.
Hence that required to oxidize organic matter	15.3 c.c.

Corresponding to 1.53 mgm. oxygen.

Therefore "required oxygen" is 1.53 × 5 = 7.65 per million.

Comparates.—As this determination deals principally with the organic carbon present, the readings are naturally high in the cases of brown peaty waters, and surface waters carrying organic matter in suspension. (See the list of analyses given above.) Average in sundry surface waters known to be pure, 1.58; known to be polluted, 3.00; average in sundry ground waters known to be pure, 0.31; known to be polluted, 1.06.

LEAD AND COPPER.—It at times becomes necessary to examine water for these poisonous metals, and the ease with which their dark sulphides may be formed provides a ready method (Miller).

Prepare a standard solution of lead nitrate, $Pb(NO_3)_2$, by dissolving 1.5990 gm. of the salt in 1 litre of distilled water. Each cubic centimetre will contain 1 mgm. metallic lead.

Place the water in a 100-c.c. "Nessler" jar; add four drops of concentrated HCl, followed by 1 c.c. of colorless ammonium sulphide, and match the tint by operating in a similar manner with measured amounts of the standard lead solution diluted to 100 c.c. This will not, of course, distinguish between copper and lead, but, inasmuch as either is objectionable, distinguishing is not commonly necessary.

In order to test the action of the water upon *lead pipe*, permit it to remain in contact with both bright and dull lead (in separate vessels) for twenty-four hours, and then examine the water as above.

IRON.—This metal is objectionable if in considerable quantity, particularly in water to be used for washing white goods and for dyeing. A knowledge of the presence of iron will, moreover, aid in guarding against an invasion of iron-secreting organisms such as crenothrix.

To determine its quantity acidify a suitable volume of the water with aqua regia; concentrate to 100 c.c.; place in a 100-c.c. "Nessler" jar; add 2 c.c. of ammonium sulphocyanate solution, and compare the depth of color produced with known amounts of standard iron solution diluted to 100 c.c. and similarly treated with ammonium sulphocyanate solution.

The *standard iron solution* is prepared by dissolving 0.1 gm. pure iron in a little HCl to which a few drops of HNO_3 have been added, and then diluting to 1 litre.

ALUM.—When examining the effluent from mechanical filters, it becomes essential to determine if any undecomposed coagulant (*i.e.*, alum) passes into the filtrate. For such purpose the "logwood test" is by far the most valuable.

Boil some logwood chips in a little water for a few minutes and drain off the resulting extract. Repeat the boiling and again discard the extract. Boil for the third time about fifteen minutes and keep the extract for use.

Place about 100 c.c. of water in a porcelain dish, add a little of the logwood extract, followed by a little acetic acid. If even a trace of alum be present in the water a violet tinge will be obtained, which will not be discharged upon addition of the acetic acid. A "blank" should always be run for comparison. The logwood extract is reliable but for a short time, especially if exposed to air. It is never safe to trust it when more than a day old.

Logwood for this test cannot be readily purchased, that obtainable from the druggists being absolutely worthless. The best method of obtaining it is personally to bore the chips from the centre of the log.

When examining the filtrate from a mechanical plant by the logwood test, it would be well to take the alkalinity also.

If the filtrate be alkaline free alum cannot be present, and the logwood reaction, if then found, is due to particles of $Al_2(OH)_6$ passing the sand bed and becoming dissolved in the reagents employed.

Lacmoid should be used as the indicator, as methyl-orange does not indicate an acidity due to alum.

BACTERIOLOGICAL EXAMINATION OF WATER.—For the accomplishing of the determinations that are here proposed, the following culture media should be carefully prepared and kept ready at hand.

Bouillon.—Take one pound of lean beef, chop it fine, and let it soak overnight in 700 c.c. water in a cool place. Strain through a cloth with the aid of gentle pressure and make up to 1 litre with water. Add 10 gm. of peptone (Witte's) and 5 gm. of common salt. Heat in a double-walled "oatmeal-boiler" until the added ingredients are dissolved. Should the medium not be clear, cool somewhat, add the white of an egg, bring to a boil without stirring, and filter while hot.

The proper reaction of the finished medium should be about + 15 (*i.e.*, an acidity equal to what would be produced by the addition of 15 c.c. of normal hydrochloric acid to 1 litre of the medium made neutral to phenolphthalein).

In order to secure such a reaction place 5 c.c. of the medium in a porcelain dish, add 45 c.c. distilled water and 1 c.c. of a solution of phenolphthalein (0.5 gm. phenolphthalein in 100 c.c. of fifty-per-cent. alcohol).

Titrate to the neutral point with N/20 NaOH or with N/20 HCl (the former will be the solution most commonly required), and from these data calculate the amount of normal HCl required to be added to the bulk of the medium in order to bring it to the desired degree of acidity, namely, + 15.

The said normal acid having been added, the "bouillon" is placed in test tubes plugged with cotton or in flasks similarly closed; the cotton plug is then covered with a small sheet of "tinfoil" to prevent evaporation, and sterilization is accomplished by heating in an "Arnold's sterilizer" for twenty minutes on three successive days.

Sterilization may be accomplished by a single heating in an autoclave to fifteen pounds pressure for fifteen minutes.

Keep the "stock bouillon" and all other stock media in a cool, dark place.

Nutrient Gelatin.—Take one pound of lean beef, chop it fine, and let it soak overnight in 700 c.c. distilled water in a cool place. Strain through a cloth and make up to one litre with distilled water. Add: Gelatin (best French), 120 gm; peptone (Witte's), 10 gm.; common salt, 5 gm. Heat in a double-walled "oatmeal-boiler" at a temperature between 35° and 40° C. until all is dissolved. Add the white of one egg, previously shaken up with about its own bulk of water, and stir thoroughly. Heat as rapidly as possible to boiling, stirring occasionally. Cover the mixture and keep the water in the outer vessel boiling during fifty minutes.

Filter, with the use of the hot-water funnel. Place 5 c.c. of the filtered medium in a porcelain dish; dilute the same with 45 c.c. water; titrate with N/20 NaOH solution, as in the case of the preparation of "bouillon," and from the data so obtained calculate what addition of normal HCl should be made to the main bulk in order to carry its reaction to the desired point, namely, + 15.

Pour the finished jelly into "Miquel" flasks or test tubes (10 c.c. in each). Plug the vessels with cotton and sterilize them in an Arnold's sterilizer for *twenty minutes* on three successive days or by a single heating in an autoclave at fifteen pounds pressure for fifteen minutes.

Sugar Bouillon.—Prepared the same as the ordinary "bouillon" except that 10 gm. of pure glucose are added with the peptone and salt. Its reaction should be neutral.

Inasmuch as the high temperature of the autoclave might partly decompose the sugar, it is better to sterilize in the Arnold's sterilizer for twenty minutes on three successive days. The best vessels in which to store "sugar bouillon" are the "Smith's fermentation tubes" in which it is to be used.

Sugar Gelatin.—Prepared like nutrient gelatin except that 10 gm. of pure glucose are added with the other ingredients. Sterilize in the Arnold's sterilizer for twenty minutes on three successive days. It is best kept in test tubes plugged with cotton; 10 c.c. in each tube.

Agar-agar.—Although plate cultures for water examination are best made by the use of "nutrient gelatin," it is sometimes convenient to employ a medium with a higher melting point. It must be noted, however, that "counts" of colonies growing upon agar must not be compared with those upon gelatin; the latter medium being more favorable to an increased growth.

To make 1 litre of agar-agar take: A. Chopped meat, 500 gm.; water, 500 c.c. Mix and place in cool place overnight, then strain through cloth. Add: Peptone (Witte's), 10 gm.; common salt, 5 gm. B. Agar-agar, 12 gm.; water, 500 c.c.

Place B in autoclave, run up to about thirty pounds of pressure, put out flame, and allow to cool until below 100° C. before opening. Let the solution of agar cool still further to about 75° C., and then mix A and B. Bring to a boil for about three minutes, neutralize, and filter. The product is an absolutely clear jelly, which never forms any precipitate. (*Ravenel's method.*)

Place the finished medium in tubes and "Miquel flasks" and sterilize as usual.

Nitrate Solution.—Dissolve 1 gm. of peptone and 0.2 gm. of KNO_3 in a litre of water. Place the solution in cotton-plugged flasks (50 c.c. in each) and sterilize.

Dunham's Solution.—Dissolve 10 gm. of peptone and 5 gm. of NaCl in a litre of water. Place the solution in cotton-plugged flasks (50 c.c. in each) and sterilize.

Empty glassware is best sterilized by a single heating for one hour to 170° C.

The pipettes used for the measurement of the water should be plugged with cotton near the end which is placed in the mouth; the whole pipette should then be placed in a suitable glass tube containing a cotton plug in its open end.

Water samples for bacteriological purposes are most conveniently taken in bulbs of glass with long thin stems, similar to the stock article in use for specific-gravity determinations. These bulbs can be sterilized by the direct Bunsen flame and sealed while hot. Upon afterward breaking off the point of the stem under water the water will enter the vessel because of the partial vacuum, and the stem can be at once resealed by using a candle flame and a blowpipe. Such bulbs are very convenient for taking deep samples, as the point of the stem can be broken by a separate string while the bulb is held by the sinking apparatus. During transportation the bulbs filled with water samples should be packed in ice.

Upon arrival at the laboratory 1 c.c. or less of the water, after thorough agitation, is transferred, by means of a sterilized pipette, to a sterile Petri dish. A tube of culture jelly (the jelly having been previously liquefied by immersing the tube in warm water at 35° C., and the open end of the tube having been held for a moment in the Bunsen flame) is then quickly poured into the Petri dish, and mixing is accomplished by tilting the dish forward and back. After the jelly has again hardened the dish should be maintained, in the dark, at a temperature of about 22° C.

When "agar" is employed it is more convenient to melt it at 100° C. and then cool it to about 40° C. before sowing.

Each individual bacterium, finding itself embedded in material supplying abundance of food, proceeds to surround itself by a multitude of its offspring, until at length the "colony" so produced becomes large enough to be seen by the naked eye. These colonies, each of which corresponds to one original bacterium, are of various sizes and shapes. Some of them do, and others do not, liquefy gelatin.

The method of sowing water samples as given above is that in common use, but preference is sometimes given to the use of conical "Miquel" flasks, usually two and one-half inches in diameter at the bottom, with a tubulated glass cap, ground at the joint (Fig. 5036). The tubulation is plugged with cotton. Such flasks receive 10 c.c. each of the culture jelly when it is first made, and are kept in stock like the test tubes. Taken to the field, they receive, on the spot, the measured amount of water, and the chances of contamination during transfer of the Petri dish and of multiplication during the journey of the water sample to the laboratory are thereby avoided. This method of working has proved very satisfactory, as no transportation of the water sample is required.

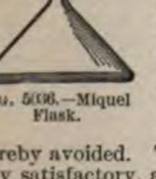

FIG. 5036.—Miquel Flask.

In place of sowing a fraction of a cubic centimetre of water, the "dilution method" conduces to greater accuracy. One cubic centimetre or 10 c.c. of the water are diluted to 100 c.c. with sterilized water and then 1 c.c. of the mixture is sowed in the medium. This is Miquel's favorite method. Of course this dilution must be done with great care, as any error is multiplied.

Counting the colonies of bacteria is undertaken forty-eight hours after the sowing, according to the official German regulations, but it is well to delay it longer or to count sooner, according as the danger may be less or greater of the colonies growing into each other and thus confusing the count.

Of course, what is required is the maximum count, and good judgment must be exercised as to when is the best time to secure it. For purposes of comparison (and usually comparison examinations are the most important form of water investigations) four days will be found a convenient interval between the sowing and the final counting of the colonies. When the number of the colonies is large, counting must be done with the aid of a ruled glass plate.

Sundry bacteria are capable of inducing a fermentative action, with evolution of gas (CO_2 and H), when sown in a medium containing one per cent. of glucose. The *Bacillus coli communis* is a prominent member of this group, and the persistent presence of many of these germs in a water is strong evidence of its contamination by intestinal products from man or the higher animals.

Tests for B. coli communis.—1. To each of ten Smith's "fermentation tubes," charged with sterile "sugar bouillon," add 1 c.c. of the water. Mix by tilting the tube, and place in the incubator at 38° to 40° C. for three days.

If any gas-forming bacteria be present, gas will collect in the closed limb of the tube, and some knowledge of the numbers of such organisms present may be gained by observing how many of the ten tubes show the reaction.

The amount of gas produced is stated in percentages of the length of the closed limb. *B. coli communis* will fill this closed limb about half full of gas, and will do so rapidly, usually ceasing to form any more after the end of the first day. Sundry other "gas-formers" act much more slowly. Therefore note the volume of gas formed during each of the three days.

The total gas will often on the third day be diminished in volume, due to solution of CO_2 in the liquid present.

To determine the CO_2, fill the bulb to overflowing with solution of KOH; close the orifice with the thumb and tilt the tube a number of times to cause the KOH to absorb the CO_2. The remaining gas is rated as hydrogen, although it contains also a little nitrogen and methane, as shown by Pennington and Küsel.

Sowings from pure cultures gave the following averages: Total gas, 35.3 per cent.; gas formed during first day (as percentage of total gas), 100 per cent.; ratio of H to CO_2, 71 to 29.

2. The liquid in the bulb of the fermentation tube must be distinctly acid to indicate *B. coli*.

3. *Indol* (C_8H_7N) is a compound belonging to the aromatic series, which produces a red color when acted upon by nitrous acid. It is formed by the breaking up of peptone by the action of putrefactive bacteria, including *B. coli*.

To test for its presence, place 25 c.c. of the water, together with 50 c.c. of sterile Dunham's solution, in a sterilized cotton-plugged flask, and keep the same in the incubator at 38° to 40° C. for three days. The high temperature will destroy common water bacteria, but will encourage the growth of the colon group.

Place 2 c.c. strong sulphuric acid and 2 c.c. of sodium nitrite solution in a 100-c.c. "Nessler" jar. Cool. Dilute with 50 c.c. water and then pour in the previously cooled incubated culture prepared above. A red coloration indicates indol, and is an additional evidence of the presence of *B. coli*.

4. Inoculate "nutrient gelatin" from the incubated culture obtained in 3. Let the plates develop as usual and observe if any of the *non-liquefying* colonies are *whitish*, with *irregular, leafy* outlines and showing lines more or less radial. Such characteristics point to *B. coli*.

5. Place a quantity of new milk in an Arnold's sterilizer for fifteen minutes, and afterward allow it to stand overnight in a cool place. Siphon off the lower layer of milk, avoiding the cream. Place it in cotton-plugged test tubes and sterilize as usual. Add to several of these

tubes 1 c.c. of the incubated culture obtained in 3, and keep in the dark at room temperature.

B. coli coagulates milk in from one to three days. Other forms usually take more time.

6. If inoculations from the colonies obtained in 4 be examined as "hanging-drop" cultures, the bacilli will be found to be motile if they be *B. coli*. This motility may be manifested, however, by only a portion of the bacilli present in the field, and its intensity will be far less than that shown by the typhoid bacillus.

7. Add 25 c.c. of the water to a flask of "nitrate solution" and place in the incubator for three days. Test the contents of the flask at the end of that time for "nitrite."

B. coli reduces the nitrate to nitrite.

A moment can be properly spent here upon the often broached topic of the recognition of the typhoid germ in water, and also a word added with reference to the diagnostic value of the demonstration of the presence of *Bacillus coli communis*.

Laws and Andrewes, in their report to the London County Council, show that the chance of discovering *B. typhosus* in sewage is exceedingly small. They entirely failed to find it in London sewage. Finally, they examined the sewage flowing (without disinfection) from the Eastern Hospital at Homeston, which same received the dejections of forty typhoid patients. Out of a whole series of samples examined from this latter source, only two colonies of *B. typhosus* were differentiated with certainty.

A similar experience has been recorded by practically all the recent observers, and consequently search for the typhoid germ in water is becoming very unusual.

The present position of this question is tersely summed up by Dr. W. H. Welch, of Johns Hopkins University: "The most which can be expected is the determination, not of the actual presence of the typhoid bacillus, but of the possibility or probability of its presence. Our principal guide at present in drawing conclusions as to the possible presence of the typhoid bacillus in suspected drinking-water is the recognition of fæcal bacteria, and more particularly of members of the colon group."

With regard to the diagnostic value of the colon group as supplying the much-needed "index of fæcal pollution," it must be stated that the group is widely distributed, and is often found in waters that a "sanitary survey" would unquestionably pronounce pure; but it cannot be denied that its persistent presence in large numbers is an indication of pollution that must not be overlooked; and, moreover, the proof of its absence serves materially to aid in formulating an opinion concerning the purity of a water.

It is, of course, possible to proceed much further than has been here outlined in the bacteriological examination of water, but for routine work it is doubtful if it pays to go beyond the tests already given. Moreover, it should be said that to make such tests of real value, they should be comparative in character; and the interpretation of results should be based upon data furnished by closely related local standards.

"Microscopical" examination of water has for its object the study of such suspended material, whether organized or not, as may be examined directly without the intervention of the "culture" methods required for bacteria. Plants and animals, dead or alive, amorphous organic material and inorganic particles of all kinds, are classified and their numbers estimated by this form of investigation. It is of especial value in determining the cause of those disagreeable odors and tastes which occur in stored water from the abundant growth of certain small aquatic plants. Concentration of the water sample is, of course, necessary in order to make a proper examination possible, and this end is accomplished by a modification of the original Sedgwick-Rafter apparatus.

This is a glass cylinder two inches in diameter, terminating in a conical base. The small cylindrical prolongation of the cone's apex is two and one-half inches long and one-half inch in diameter. A perforated rubber stopper, with its hole covered by a disc of fine bolting-cloth, is fitted to the smaller end of the funnel and about three-fourths inch of carefully screened fine sand (between eighty and one hundred mesh) is poured into the narrow tube and wet down with distilled water. From 250 to 500 c.c. of the water under examination are now permitted to filter through the sand. After the water has run through, the sand with the material strained off by it is washed into a test tube by 5 c.c. of distilled water delivered from a pipette. The organisms, sinking in the test tube much more slowly than the sand grains, may be decanted, with the water in which they float, into a second test tube. From this decanted portion, after agitation, 1 c.c. is delivered by a pipette to a covered "counting cell," which it completely fills. The objects discovered in this counting cell will, if multiplied by five, give the total number originally existing in the entire volume of water filtered.

It is manifestly impossible, in an article such as this, to dwell at length upon the very extensive subject of microscopic examination; therefore for purposes of general differentiation recourse must be had to the writings of biologists who have made such work a specialty.

William P. Mason.

WATER-GAS, POISONING BY.—Water gas is a mixture of carbon monoxide and hydrogen with some nitrogen and carbon dioxide, obtained by the action of steam on highly heated carbon (*e.g.*, coke or anthracite). It is nearly odorless and burns with non-luminous flame. For use as an illuminant, it is enriched; that is, charged with hydrocarbons from petroleum or bituminous coal. In this form it has come into extensive use. Owing to the highly poisonous character of carbon monoxide as compared with the hydrocarbons that form the bulk of the older "coal gas," a great increase in fatalities from the inhalation of illuminating gas has been noticed in the mortality statistics of late years. The characteristic effect of carbon monoxide is its affinity for hæmoglobin, with which it forms a compound that cannot be broken up by free oxygen. Hence, even a small amount of carbon monoxide in the inspired air will cause a steady accumulation of the toxic material until so much of the hæmoglobin is rendered inactive that death results from a chemical asphyxia. The symptoms are marked muscular weakness, rapid pulse, flushed face, and a strong tendency to sleep. The blood becomes abnormally red, the breathing becomes stertorous, and the patient dies from failure of respiration. If the patient be rescued before the condition is far advanced, the return to consciousness is slow, even under treatment, and a fatal result from brain disease may yet occur. In advanced cases, red spots are noted on the skin. The blood putrefies much more slowly than normal blood. The fatal period is somewhat uncertain, but may be several hours. The treatment is not satisfactory. Artificial respiration does little good. Inhalation of oxygen under pressure has been proposed, but this method does not promise much. Transfusion of blood has been successful in experiments on animals. Good results have been claimed for the administration, by the stomach and hypodermically, of hydrogen dioxide, but this seems doubtful. Hot applications should be used to restore normal temperature. The bright redness and slow putrefaction of the blood are important post-mortem data. Several chemical tests have been proposed, but they are not very satisfactory in actual practice, as ordinary illuminating gas contains several active substances.

Henry Leffmann.

WATSON'S SPRINGS.—Greene County, Georgia.

POST-OFFICE.—Maxey's boarding-houses and cottages.

These springs are located eleven miles north of Greensboro, on the Georgia Railroad, and eight miles west of Maxey's Depot, on the Athens branch of the Georgia Railroad. The group is one-quarter of a mile from the Oconee River, which will be navigable at this point when the government works on the river are completed.

he springs are reached by private conveyance from the oints above mentioned. The scenery in the neighbor-ood of the springs is varied and the climate delightful, e temperature rarely falling below the freezing point winter or rising above 90° F. in summer (95° F. is the ighest temperature known). The springs are four in umber, viz.: the "Sulphur" Spring, the "Chalybeate," e "Alum," and the "Ice" Spring. The following par-al analysis of two of the springs was made some years o by Dr. J. R. Duggan:

The Sulphur Spring contains calcium carbonate, potas-um carbonate, iron carbonate, potassium sulphate, so-um sulphate, sodium chloride, silicic acid, hydrogen lphide gas, and carbonic acid gas. The temperature the water is 59° F.

The Chalybeate Spring contains iron carbonate, mag-sium carbonate, sodium chloride, potassium sulphate, lcium sulphate, and silica. The temperature of the ater is 61° F.

The "Ice" spring has not been analyzed, but its waters delightfully cold and refreshing and palatable at all s. The sulphur and chalybeate springs yield about gallon of water per minute. Their waters are stated e highly efficacious in rheumatism and dyspepsia, and enal, cutaneous, and blood diseases.

James K. Crook.

AUKESHA MINERAL SPRINGS.—Waukesha nty, Wisconsin.

ST-OFFICE.—Waukesha. Hotels and boarding-ses.

CCESS.—Viâ Chicago and Northwestern, Chicago, waukee, and St. Paul, and Wisconsin Central Rail-d. An electric line is also being built from Milwau-

aukesha, the county seat of Waukesha County, is ted sixteen miles west of Milwaukee, and ninety-t miles northwest of Chicago. The elevation here is t 800 feet above tide-water. The surrounding coun-s of a rolling character, well wooded and has a sandy, elly soil. The natural advantages of the place have e it a general society centre of the Northwest during summer season. The usual population, of about -four hundred, is increased during the hot months re than ten thousand. In the year 1895 there were hundred and forty-three clear days, one hundred and y partially cloudy, and ninety-two cloudy days. summer weather is usually of a delightful character, quite free from days of oppressive heat. The aver-annual rainfall from 1892 to 1895, inclusive, was inches. The village contains eleven hotels and more than forty boarding-houses. In addition, the houses of private citizens are often thrown open to visitors. Among the best-known hotels are the Fountain Spring House, which accommodates 800 guests, the Park, 300; the Spring City, 250; National, 150; Terrace, 100, etc. Most of the hotels maintain bands during the season. Open-air public concerts are also given morning and evening. There is one theatre in the place besides two public halls. The Fox River runs through Waukesha, and is large enough for row boats. This is a region of lakes, there being no less than thirty-six in Waukesha County, the most remote being only eighteen miles distant. The lakes are surrounded by hotels and cottages, and during the summer they constitute a vast picnic ground. The prime attraction of Waukesha, however, is found in the great group of mineral springs located here. The waters of these springs are chiefly alkaline, chalybeate, and calcic. They have become known throughout the United States. Following are analyses of some of the most important:

Other well-known springs at Waukesha are the "White Rock," "Glen," "Horeb," "Gibson," "Siloam," "Mineral Rock," and "Vitaqua." It will be observed that the principal ingredients of all these waters is the bicarbonate of magnesium. Their action in the system is antacid, mildly laxative after continuous use, and diuretic. They have a useful application in dyspepsia, abdominal engorgement, Bright's disease, diabetes, and bladder troubles. Some of them are excellently adapted for table use.

James K. Crook.

WAX; BEESWAX.—(*Cera Flava*, U. S. P., B. P., P. G.); A peculiar, concrete substance, prepared by *Apis mellifica* L. (Ord. *Hymenoptera*).

Wax is an animal product secreted by bees under the rings of the abdomen, where it accumulates, when the insects are comb-making, in scales or flakes. These flakes are disengaged by the bees, and, with jaws and legs, moulded into that remarkable structure, the honeycomb. It appears to be an analogue of the sebaceous secretion of the skin. The wax is obtained by depriving the comb of its honey by draining and pressing, and is purified by melting one or more times in boiling water and cooling. It is then melted and cast in large solid cakes.

Wax is too familiar to need description, were it not for its very frequent adulteration, which unfortunately is not always easily detected. The Pharmacopœial description and tests are as follows: "A yellowish or brownish-yellow solid, having an agreeable, honey-like odor, and a faint, balsamic taste. It is brittle when cold, but becomes plastic by the heat of the hand. It melts at 63°–64° C. (145.4°–147.2° F.), and congeals with a smooth and level surface. Specific gravity, 0.955–0.967. It is insoluble in water, but soluble in 35 parts of ether and in 11 parts of chloroform; also soluble in the oil of turpentine and in fixed or volatile oils. Cold alcohol dissolves it only partly, but it is almost completely soluble in boiling alcohol." Boiled with a solution of soda, wax does not saponify like the fats and resins, and their mixture with wax can be detected in this way; if the liquid so boiled, after the wax has been separated by cooling, remains turbid, or gives a precipitate when acidulated with hydrochloric acid, fat, resin, soap, or something of that kind is present. "If 5 gm. of wax be heated, in a flask for fifteen minutes, with 25 gm. of sulphuric acid, to 160° C. (320° F.), and the mixture diluted with water, no solid, wax-like body should separate (absence of paraffin)."

The composition of wax is: *Cerin*, an ether of cerotic acid and ceryl alcohol, $\left.\begin{matrix}C_{27}H_{53}O\\C_{27}H_{55}\end{matrix}\right\}O$, ten per cent.; and *myricin*, an ether of palmitic acid and myricyl alcohol, $\left.\begin{matrix}C_{16}H_{31}O\\C_{30}H_{61}\end{matrix}\right\}O$, ninety per cent. ("Encyclopædia Britannica"), together with traces of coloring and aromatic substances. White wax (*Cera Alba*, U. S. P.) is yellow wax bleached, usually by being cut into thin ribbons or shreds and exposed for a few weeks to the atmosphere and sunlight, being also frequently watered. It may also be bleached by the less desirable method of treatment with the oil of turpentine or some chlorine solution. It is a yellowish-white solid, somewhat translucent in thin layers, having a slightly rancid odor and an insipid taste, answering otherwise nearly to the description and tests given above.

Action and Uses.—Wax is insoluble in the body, and therefore exerts only a mechanical action upon it. Its use internally is entirely obsolete. Formerly it was occasionally recommended for diarrhœa or dysentery, and later, as a pill-coating. Its plasticity and very great permanence make it useful as a temporary tooth-filling where the cavities are tender and away from the grinding surfaces. Its principal employment in medicine, however, is as a component of cerates (which derive their name from it), plasters, and ointments, to which it gives durability and consistence. It is perfectly unirritating.

The most important uses of wax are ceremonial and domestic—candles and mechanical moulding and modelling.

Allied Substances.—Chinese wax, secreted by Coccus ceriferus upon a Chinese ash; a hard, translucent, spermaceti-like substance; Japanese, from the surface of the fruits of several species of Rhus; bayberry wax and several other vegetable products. See also *Spermaceti*.

W. P. Bolles.

WAXY DEGENERATION.

See *Amyloid*, and *Necrosis*.

WEIGHTS AND MEASURES.

—Balances and measures of capacity are brought into constant use in chemistry, pharmacy, and medicine. Means for the accurate determination of values are indispensable to science, industry, and commerce, and the development of scientific metrology is a concomitant of advancing civilization.

Old Weights and Measures.—The expressions used in ancient writings to indicate size, or quantity, the oldest units of measure, and the origin of decimal arithmetic, all have reference to the human body and its members. Bulk was measured by armfuls, handfuls, pinches; linear measure was expressed in such terms as "the height of a man," the fathom, stride, forearm (cubit), foot, hand, palm, finger, thumb, nail; the oldest expressions of weight had reference to loads or burdens; and decimal arithmetic had its origin in the number of fingers on the human hand. Seeds were later used as standards of comparison for the determination of weight, and also for linear measure; the "karat" and the "grain" originated in this manner. When coins were introduced they were frequently employed as weights, and the intimate relations which weights and coins sustained to each other are shown by the use of the same words to designate units of weight and monetary units, as "drachma," "livre," "pound," "mark," etc.

Commercial intercourse between different countries helped to spread the various weights, measures, and money from one country to another; but in the absence of proper governmental regulation, and in consequence of national prejudices and conflicting interests, the systems and units suffered changes which created confusion. The same, or very similar, names were given to units of differing values, and different methods of subdivision increased the diversity. This chaotic condition of the weights and measures of the civilized world is sufficiently shown in the following tables:

Pounds and Grains Used at Various Times in Different Countries.

Country or locality.	Value of the pound in grams.	Number of grains in each pound.	Value of the grain in grams.
France ("livre métrique")	500.0	9,216	0.054
Germany ("zollpfund")[1]	500.0		
France ("livre poids de marc")	489.5		
England and the United States (avoirdupois pound)	453.59	7,000	.065–
Sweden[2]	425.0		
Austria	420.0	5,760	.073+
Netherlands and Switzerland	375.0	5,760	.065+
England and the United States (troy pound and apothecary's pound)	373.24+	5,760	.065–
Amsterdam	371.0		
Bavaria and Greece	360.0	5,760	.063–
Poland	358.5		
Russia	358.3	5,760	.062+
Norway	357.85–	5,760	.062+
"Nüremberg Pound"[3]	357.661–	5,760	.032+
Sweden	356.25–	5,760	.061–
Prussia	350.8–	5,760	.061–
Spain	345.1	6,912	.050–
Portugal and Brazil	344.25		
Tuscany	339.5	6,912	.049+
Papal States	339.7		
Turin	322.0	6,912	.048+
Naples and Sicily	320.8	7,200	.045–
Sardinia	307.4	5,760	.053+
Venice	301.2	5,760	.052+
Mons	279.0		
Baden	214.25		

[1] Subdivided into 30,000 "korn."

[2] Subdivided into 10,000 "korn."

[3] Officially recognized by many pharmacopœias, among which were those of Nüremberg, Finland, Hamburg, Schleswig-Holstein, Russia (military pharmacopœia of 1840), Baden, Hanover, Hesse, Bremen, Lübeck, Nassau, etc.

The ounces, drachms, and scruples, of course, varied as much. The pound was generally subdivided into 12 ounces; but sometimes into 16; the ounce into 8 drachms, but one of them into 16; the scruple into 20 grains, but sometimes into 24.

Varying Value of the Foot.

	Value in millimetres.
Hesse (the Grand Duchy)	250
Saxony	283
Frankfurt a. M	284
Brunswick	285
Würtemberg and Hamburg	286

Baden	300
England	305
Prussia (Rheinish)	313
Norway	314
Austria	316
Paris	324

In England alone there have been four different kinds of gallons, quarts, and pints.

Legislation relating to weights and measures aimed to fix the values of existing units so as to prevent variation

[illegible]

[illegible]

[illegible]

tion as well as of weights, measures, and money. Notwithstanding the universal inclination of the untutored human mind to count upon the fingers and toes, and despite the universality of the decimal system of numeration as the result of that primitive instinct, mankind did not adopt decimal division and multiplication in regard to measurements of length, surface, volume, weight, money, or time; but the subdivisions and multiples adopted were by 2, 4, 8, 16, and 32, and by 3, 12, 24, and 60.

The number 12 has been recommended as a periodical number, because it is evenly divisible by 2, 3, 4, and 6; and 8 has been proposed, because, without being either too small or too large, it is the cube of 2, which is the smallest number above the unit; one-half of 8 is the square of 2, and three successive divisions by 2 gives 1 as the last quotient.

Octonary notation would, of course, be quite as easy as decimal notation, and more natural. It would require but eight figures including the cypher; two figures would be used to write eight, and three figures to write eight times eight, etc., and we would have an octonal point instead of the decimal point.

To show the most common subdivisions of weights and measures, the following will suffice:

Distance Measure: 1 mile = 8 furlongs. 1 furlong = 40 rods. But furlongs and rods are not so often mentioned as "half miles," "quarter miles," eighths of a mile, etc.

For shorter linear measures we find: 1 yard = 3 feet. 1 foot = 12 inches.

The yard is used most frequently in measuring cloth, but no one uses such expressions as "a yard and one foot or "a yard and one foot and six inches"; we would instead say "a yard and a third," or "a yard and a half." Halves, quarters, and eighths of a yard are more commonly referred to than any other fractions when the measure need not or cannot be exact, notwithstanding the subdivision of the yard into three feet or thirty-six inches. But the yard was derived from the length of the arm of King Henry I., in 1101; and it was divided into three feet, because the third of it was not very far from the length of a man's foot; and the subdivision of the foot into twelve inches was continued, because one-thirty-sixth of the yard was about the length of a man's thumb from the end to the first joint. In other words, these units were adopted for the sake of preserving the use of the valuable object lessons afforded by the members of the body, rather than to insure the most convenient and valuable mathematical results. Inches are subdivided into halves, fourths, eighths, sixteenths, and thirty-seconds, more frequently and naturally than into tenths. And yet the foot has, in some countries, been subdivided into ten inches instead of twelve, and each inch into ten lines instead of twelve, in obedience to the demand that the metrological subdivisions shall agree with the arithmetic.

Land Measure.

1 square mile = 640 acres.
1 acre = 4 roods.

But we speak commonly of half acres and quarter acres, and not of roods.

Volume Measure.

1 bushel = 4 pecks or 8 gallons.
1 peck = 2 gallons or 8 quarts.
1 gallon = 4 quarts or 8 pints.
1 quart = 2 pints or 8 gills.
1 pint = 4 gills or 16 fluidounces.
1 gill = 4 fluidounces or 32 fluidrachms.
1 fluidounce = 8 fluidrachms.
1 fluidrachm = 60 minims.

In these subdivisions there was nothing to prevent the consistent application of the natural inclination to divide the larger units into two, four, eight, sixteen, or thirty-two parts, until the fluidrachm was reached; but the fluidrachm was subdivided into sixty minims, because it was desired to make the subdivisions of the fluidounce, which was used only by physicians and apothecaries, parallel with the subdivisions of the ounce.

In the imperial pint there are twenty fluidounces instead of sixteen, as the unavoidable result of making the avoirdupois ounce commensurate with the fluidounce, while the gallon was made to represent the volume of ten pounds of water.

Avoirdupois Weight.

1 pound = 16 ounces.
1 ounce = 16 drachms or 437½ grains.

But the awkward subdivision of the ounce into 437.5 grains was simply the direct result of combining portions of two different systems, and avoirdupois weight did not originally include any smaller unit than the drachm. We no longer make use of the avoirdupois drachm, but do make use of halves, quarters, and eighths of the avoirdupois ounce, having weights of these denominations among the sets in common use in our shops.

Troy Weight.

1 pound = 12 ounces, or 240 pennyweights.
1 ounce = 20 pennyweights or 480 grains.
1 pennyweight = 24 grains.

Old Medicinal Weights.

1 pound = 12 ounces.
1 ounce = 8 drachms or 24 scruples.
1 drachm = 3 scruples or 60 grains.
1 scruple = 20 grains.

Sometimes the scruple contained twenty-four grains.

From the above examples it will be seen that two principal considerations have determined the subdivision of the larger into smaller units, namely: (1) Capacity for continued integral bisection down to unit; and (2) divisibility by a variety of aliquot parts.

The Romans divided their acre, their foot, and their pound, each into twelfths (*unciæ*, from which our "ounce" and "inch"); the signs of the Zodiac, the division of the year into twelve months, and of the day into twelve hours, and the use of the "dozen" and the "gross" also show that the number twelve has, next to eight, been a favorite periodical number. The number sixty has also been much used, because divisible into a great variety of aliquot parts. In the division of the earth's longitude and latitude, and in the division of time, the number sixty has been found valuable.

But we find no subdivisions by ten in the old methods of dividing measures, weights, time, or money.

The following table forcibly illustrates the natural tendency to binary and quarternary subdivision, and at the same time the redundance of units, which is a common fault in the several systems of weights, measures, and money.

In Baden the weights at one time used were:

4 richttheilen = 1 gränchen.
4 gränchen = 1 grau.
4 granen = 1 karat.
4 karate = 1 pfennig.
4 pfennig = 1 quentchen.
4 quentchen = 1 loth.
2 lothe = 1 unze.
4 unzen = 1 vierling.
2 vierling = 1 mark.
2 mark = 1 pfund.

AMERICAN WEIGHTS AND MEASURES.—No civilized country has failed to enact complete and specific laws establishing standards for the weights and measures used by its people, except the United States of America. All other nations have laws enumerating the several units which shall be used, establishing their relations to each other, fixing their respective values, and providing for the construction and proper preservation of prototypes or models by which the weights and measures intended for the use of the people shall be standardized. In the United States there is no law for the establishment of any weights or measures other than one declaring a certain copy of the British prototype troy pound to be the standard "conformably to which the coinage shall be regulated." The weights and measures in actual use throughout the United States are the avoirdupois weight of the present British "Imperial System;" the troy weight and apothecaries' weight, which was abolished in England by a law passed in 1824, to take effect January 1st, 1826; the English linear measures; and the wine measures and Winchester measures, abolished in England simultaneously with the abolition of the apothecaries' weights. No law now exists, in this or any other country, which directly fixes the value and subdivisions of the liquid measures, the dry measures, or the medicinal weights and measures used in the United States.

The only United States laws relating to weights and measures are these: "For the purpose of securing a due conformity in weight of the coins of the United States, the brass troy pound procured by the minister of the United States at London, in the year 1827, for the use of the Mint, and now in the custody of the Mint at Philadelphia, shall be the standard troy pound of the Mint of the United States, conformably to which the coinage thereof shall be regulated." (R. S., 3548.)

By the act of July 28th, 1866, it was enacted that "it shall be lawful throughout the United States of America to employ the weights and measures of the metric system; and no contract, or dealing, or pleading in any court shall be deemed invalid or liable to objection because the weights or measures expressed or referred to therein are weights or measures of the metric system." (R. S., 3569.)

Tables of equivalents, showing the relations of the metric weights and measures to those in common use, were also made part of the law of 1866. (R. S., 3570.) The legal equivalents may be said to fix indirectly the values of our mile, yard, foot, inch, acre, wine-gallon, bushel, peck, quart, gill, fluidounce, fluidrachm, avoirdupois pound, ounce, and grain, with reference to the units of the metric system; but the equivalents thus established, however sufficient for the purposes for which they are intended, are inconsistent as well as inexact; they do not suffice to establish the weights and measures which may be lawfully used; they do not fix the values and subdivisions of the units sanctioned by usage and in common law, except indirectly and partially.

On the day preceding the date of the executive approval of the act to render the use of the metric system permissive, Congress passed a joint resolution requiring the Secretary of the Treasury to furnish to each State of the United States "one set of the standard weights and measures of the metric system for the use of the States, respectively;" but we have no legalized standard metre and standard kilogram, any more than we have legalized prototype standards of the weights and measures in common use.

The *present ultimate standards* upon which all weights and measures employed in the United States are based are the American national prototype standards of the metre and the kilogram, made of irido-platinum, received by the American Government from the International Bureau of Weights and Measures (near Paris) in 1890, which are in the custody of the National Bureau of Standards at Washington.

The American *yard* is defined to be equal to $\frac{3.600}{3.937}$ metre; the American commercial *pound* is defined as being equal to $\frac{700,000,000}{1,543,235,639}$ kgm.; and the American liquid *gallon* is the volume of 3,785.434 gm. (58,418.144 grains) of water at the temperature of its maximum density, weighed *in vacuo.*

While the liquid gallon is designed to be a *volume* of 231 cubic inches, it is determined or adjusted *by weight* on the assumption that 252.892 grains of water, at its maximum density, weighed *in vacuo*, measures one cubic inch. This value is derived from the accepted equivalents of the metre in inches and of the kilogram in grains, coupled with the assumption that the mass of one cubic decimetre of water is identical with that of the actual standard kilogram.

Equivalents.

1 metre = 39.3700 inches.
1 yard = 0.914402 metre.

1 litre = 0.26417 liquid gallon.
1 gallon = 3.785434 litres.
1 fluidounce = 29.5737 millilitres.

1 kgm. = 2.20462 pounds, or to 15,432.35639 grains.

1 pound = 453.5924277 gm.
1 commercial ounce = 28.3495 gm.
1 medicinal ounce = 31.10348 gm.
1 grain = 64.7898 mgm.

1 fluidounce of water weighs 29.5737 gm., or 456.392 grains.
1 medicinal ounce of water measures 31.10348 millilitres, or 504.829 minims.

BRITISH WEIGHTS AND MEASURES PRIOR TO 1826, AND NOW USED IN THE UNITED STATES.—The weights and measures in use in England, prior to 1826, were the following. They are the weights and measures in common use in the United States at this time, except the beer measures, which are no longer used anywhere.

Linear Measures.

1 league = 3 miles = 5,280 yards = 15,840 feet.
1 mile = 8 furlongs = 1,760 yards = 5,280 feet.
1 furlong = 10 chains = 40 poles, or perches, or rods = 220 yards = 660 feet.
1 chain = 4 poles, or perches, or rods = 22 yards = 66 feet.
1 pole, or perch, or rod = 5½ yards = 16½ feet.
1 yard = 3 feet = 36 inches.
1 foot = 12 inches.

Superficial Measures.

1 square mile = 640 acres.
1 acre = 4 roods = 10 square chains = 160 square poles = 4,840 square yards = 43,560 square feet.
1 rood = 40 square poles = 1,210 square yards = 10,890 square feet.
1 square pole = 30¼ square yards = 272¼ square feet.
1 square yard = 9 square feet.
1 square foot = 144 square inches.

Cubic Measures.

1 cubic yard = 27 cubic feet.
1 cubic foot = 1,728 cubic inches.

Dry or Winchester Measures.

1 bushel = 4 pecks = 32 quarts = 2,150.42 cubic inches.
1 peck = 2 gallons = 8 quarts = 537.6 cubic inches.
1 gallon = 4 quarts = 8 pints = 268.8 cubic inches.
1 quart = 2 pints = 67.2 cubic inches.
1 pint = 33.6 cubic inches.

Beer Measure.

1 hogshead = 2 barrels = 72 gallons.
1 barrel = 36 gallons.
1 gallon = 4 quarts = 8 pints = 282 cubic inches.
1 quart = 2 pints = 70.50 cubic inches.
1 pint = 35.25 cubic inches.

Wine Measure.

1 hogshead = 2 barrels = 63 gallons.
1 barrel = $31\frac{1}{2}$ gallons.
1 gallon = 4 quarts = 8 pints = 231 cubic inches.
1 quart = 2 pints = 57.75 cubic inches.
1 pint = 4 gills = 28.875 cubic inches.
1 gill = 7.219 cubic inches.

Medicinal Fluid Measures.

1 gallon = 4 quarts = 8 pints = 128 fluidounces = 231 cubic inches.
1 quart = 2 pints = 32 fluidounces.
1 pint = 16 fluidounces = 128 fluidrachms.
1 fluidounce = 8 fluidrachms = 480 minims.
1 fluidrachm = 60 minims.

Measures of Weight for General Merchandise.

(Avoirdupois.)

1 ton = 20 hundredweight = 2,240 pounds.
1 hundredweight = 8 stones = 112 pounds.
1 stone = 14 pounds.
1 pound = 16 ounces = 7,000 grains.
1 ounce = 16 drachms = $437\frac{1}{2}$ grains.
1 drachm = $27\frac{11}{32}$ grains.

Measures of Weight for Precious Metals, Jewels, and Coin.

(Troy.)

1 pound = 12 ounces = 240 pennyweights = 5,760 grains.
1 ounce = 20 pennyweights = 480 grains.
1 pennyweight = 24 grains.

Measures of Weight for Medicines.

1 pound = 12 ounces = 5,760 grains.
1 ounce = 8 drachms = 24 scruples = 480 grains.
1 drachm = 3 scruples = 60 grains.
1 scruple = 20 grains.

THE BRITISH IMPERIAL SYSTEM.—The English weights and measures were reconstructed in 1824, when a law was passed which went into effect January 1st, 1826, establishing the "Imperial System of Weights and Measures," which is at the present time still in force. It includes the linear measures previously employed and the avoirdupois pound, the value of which was defined to be $\frac{7000}{5760}$ of the old standard troy pound of brass made in 1758. The new feature of the Imperial system was the Imperial gallon and its subdivisions, the old corn, beer, wine, and medicinal measures being replaced by the

Imperial Measures of Capacity.

1 bushel = 4 pecks = 8 gallons [= 2,218.191 cubic inches].
1 peck = 2 gallons = 8 quarts [= 554.548 cubic inches].
1 gallon = 4 quarts = 8 pints [= 277.274 cubic inches].
1 quart = 2 pints [= 69.3185 cubic inches].
1 pint = 20 fluidounces [= 34.65925 cubic inches].
1 fluidounce = 8 fluidrachms [= 1.733 cubic inches].
1 fluidrachm = 60 minims.

One of the carefully constructed copies (made of bronze) of the former standard yardstick, which had been destroyed, was declared to be the new standard, and a new avoirdupois pound-weight of platinum was made under the supervision of Prof. W. H. Miller, which, by the law of 1855, was declared to be "the legal and genuine standard measure of weight, and shall be, and be denominated, the Imperial Standard Pound Avoirdupois, and shall be deemed to be the only standard measure of weight from which all other weights and other measures having reference to weight shall be derived, computed, and ascertained, and one equal seven-thousandth part of such pound avoirdupois shall be a grain, and five thousand seven hundred and sixty such grains shall be, and be deemed to be, a pound troy. If, at any time hereafter, the said Imperial Standard Pound Avoirdupois be lost or in any manner destroyed, defaced, or otherwise injured, the Commissioners of Her Majesty's Treasury may cause the same to be restored by reference to, or adoption of, any of the copies," provided and available for that purpose.

Thus the avoirdupois pound, which was before based upon the troy pound-weight, became, in 1855, the only basis for all weights, including the troy weight, and also became the basis for the imperial gallon, which was defined to be the volume of ten avoirdupois pounds of pure water at 62° F.

DECIMAL WEIGHTS AND MEASURES.—The first scientific decimal system of weights and measures ever presented was of American origin, being devised and recommended to the House of Representatives of the United States, July 13th, 1790, by Thomas Jefferson, who was then Secretary of State. Mr. Jefferson had been the American Minister to Paris, where he resided during the period of the great Revolution. He had, therefore, come into direct intercourse with the Bishop of Autun and other great men, who were inspired with the grand idea of establishing a common language of weights, measures, and money for the whole world. Mr. Jefferson proposed as a basis for his new system the length of a rod swinging seconds of time in latitude 45°, one-fifth of that length to be called the new foot. This new foot was about one-fourth inch shorter than the English foot. It was to be divided into ten inches, each inch into ten lines, and each line into ten points; ten feet was to be called a decade, ten decades a rood, ten roods a furlong, and ten furlongs a mile. A new cubic foot was to be the new bushel, the weight of the new cubic inch of water was to be the new ounce, and one ounce of silver $\frac{11}{12}$ fine was to be the new dollar.

Thomas Jefferson's decimal system of weights and measures was in every way as meritorious as the metric system, but it was not adopted. Other decimal systems have been proposed at various times, but none has been used except—

The Metric System.—A new system of weights and measures was constructed in 1791, with the view of its ultimate universal adoption. It was not the work of one mind. It was the legitimate offspring of the times. In its conception and development, as in its steadily increasing domain, no nation can claim it as its own.

Its basis was the length of the earth's circumference through the poles. The Dutch astronomer, Huygens, had already, in 1685, recommended the length of the meridian as a suitable standard for measures of length. The distance from the equator to the pole having been measured along the surface of still water, one ten-millionth part of that length was denominated a METRE, and a platinum rod was made by Borda to represent the metre. The *theoretical metre* is one forty-millionth part of the length of the terrestrial meridian, and the *actual metre* is the distance between the ends of Borda's platinum rod at 0° C. They are generally supposed to be identical, but some physicists deny this. Be that as it may, the real basis of the metric system is the prototype platinum metre and not the length of the meridian; but this does not detract from the merits of that grand system. The value of the metric system depends upon the following characterisics: (1) Its construction is in perfect harmony with our present arithmetical notation, the multiples and subdivisions of all its units being in decimal progression. (2) The units of length, surface, capacity, and weight, all bear simple relations to each other, respectively, all being derived from the same primary standard, the metre. (3) Each volume unit of the metric system has a corresponding weight unit with which it is commensurate when referring to water, which is the connecting link between measures of extension and measures of weight, and the standard unit used for the expression of specific weight. Thus the units of weight and volume of the metric system are not merely parallel, but their values are readily interconvertible through the specific weights and specific volumes of the substances measured or weighed.

The word "metre" is derived from the Greek, *μέτρον*, measure, and the term "metric system" from the metre.

There are only five standard units of the metric system. These are:

The *metre*, for linear measure; the *are*, for land measure; the *stère*, for large bulks; the *litre*, for smaller bulks; the *gram*, for weights;

The *are* is the square of ten metres, or a square dekametre.

The *stère* is the cube upon one metre, or a cubic metre.

The *litre* is the cube upon one-tenth of a metre, or a cubic decimetre. But, as all capacity measures are in reality made or adjusted by means of weighing, the actual litre is the volume of one kilogram of water at 4 C. in vacuo.

The *gram* is the weight of one one-thousandth part of one litre (1 c.c.) of water at 4° C. (39.2° F.) *in vacuo*.

Secondary and additional units are obtained by decimal multiplication or division, and the names of these subordinate units are constructed by the use of certain Greek and Latin numerals in the form of prefixes. These prefixes are as follows:

Myria-, meaning ten thousand.
Kilo-, meaning one thousand.
Hekto-, meaning one hundred.
Deka-, meaning ten; and
Deci, meaning one-tenth.
Centi-, meaning one one-hundredth.
Milli-, meaning one one-thousandth.

Of these prefixes, only two are very much employed—namely, "kilo-" and "milli-." The prefix "centi-" is also used to some extent; the rest of the prefixes are not only as superfluous as the "eagle," the "dime," and the "mill" in American money, but they burden the metric system.

"Kilometre" means a one-thousand-metre, or one thousand metres; kilogram is one thousand grams; 0.005 gm. is 5 mgm.; a centimetre is $\frac{1}{100}$ metre, etc.

It is more convenient to say "ten metres" than to say "one dekametre," but less convenient to say "one one-thousandth of a gram" than to say "one milligram." The choice of expression is, therefore, to some extent governed by euphony and convenience. But there is a redundance of units in the metric system which has doubtless retarded its introduction.

The orthography and pronunciation of the metric units are modified in each country according to the language of the people. In France the spelling and pronunciation are, of course, French, as mètre, litre, and gramme; in Germany they are German, being meter, liter, and gramm; in English-speaking countries and in Sweden we say and write metre, litre, and gram; Spaniards write gramo, and Russians gramma; etc. In our country the word centimetre should not be pronounced *sangtimátre* any more than cent should be pronounced *sangt*, or the word gas-metre *gas-mátre*.

In abbreviating the metric terms there is unfortunately no uniformity of practice. The United States Pharmacopœia has adopted C.c. for cubic centimetre and Gm. for gram, and these are convenient and safe.

The metric system presents the following tables of measures and weights:

Linear Measures.

1 Myriametre	= 10,000		metres.
1 Kilometre	= 1,000		"
1 Hektometre	= 100		"
1 Dekametre	= 10		"
1 METRE	= 1		metre.
1 Decimetre	=	.1	"
1 Centimetre	=	.01	"
1 Millimetre	=	.001	"

In addition to the above units microscopists employ the "micro-millimetre," which is 0.001 millimetre.

Volume Measures.

1 Kilolitre	= 1,000		litres.
1 Hektolitre	= 100		"
1 Dekalitre	= 10		"
1 LITRE	= 1		litre.
1 Decilitre	=	.1	"
1 Centilitre	=	.01	"
1 Millilitre	=	.001	"

The only volume units employed by chemists, pharmacists, and physicians are the litre and the cubic centimetre. The cubic centimetre is practically identical with the millilitre.

Weights.

1 Kilogram	= 1,000		grams.
1 Hektogram	= 100		"
1 Dekagram	= 10		"
1 GRAM	= 1		gram.
1 Decigram	=	.1	"
1 Centigram	=	.01	"
1 Milligram	=	.001	"

In medicine and pharmacy the gram and the cubic centimetre are the most important metric units, and to express their close relationship the cubic centimetre has been very appropriately termed a "fluigram." The milligram is also indispensable.

COMPROMISE SYSTEMS.—Admiration for the metric system and its evident practical superiority were not sufficient to insure its rapid introduction. The old systems, however awkward and unscientific, were not to be displaced except under compulsion. In countries where legislation is the expression of the popular will the metric system has not yet been adopted for general use, nor was it easy to introduce it in any country. The prejudice against the foreign sound of the terms applied to the metric units proved so strong an obstacle that in some countries new names were invented, as in Italy and Greece, and even the names of old units were applied to the new values which the metric units represented.

In France, where the new system was first introduced by law, there were afterward compromises made between the old and the new weights and measures.

Various attempts were made in different countries to establish simple relations between the units of the old systems of weights and measures and the metric units, especially the weight units. The old systems were also changed so as to connect units of the same kind by decimal multiplication and division.

The German "Zoll-Pfund" was made equal to 500 gm. It was divided into 30 "loth"; but the loth was divided into 10 "quentchen," the quent into 10 "cents," and the cent into 10 "korn." Bremen and Hamburg had the Zoll-Pfund divided into tenths, hundredths, and thousandths, called "Unzen," "Neuloth," "Quinten," and "Halbgrammen." Sweden had a pound equal to 425 gm. and divided it into 100 "ort," each ort being subdivided into 100 "korn." Thus the Swedish korn differed greatly from the Prussian korn, and the quint of Bremen and Hamburg was 5 gm., while the quent of Prussia was but $1\frac{2}{3}$ gm.

Decimal systems of linear measure were also devised and used.

But these compromise systems had none of the merits of the metric system, except their partly decimal character; no simple relations existed between the units of linear measure, the units of capacity, and the units of weight, respectively. Hence they were short-lived.

SUITABLE UNITS.—The number and size of the units of weight and measure are important considerations. There are often too many units of each kind of measure. Baden at one time had fifteen different weight units. In order to have convenient units for all ordinary purposes, it is not necessary that they should be near each other in value as they are in the metric system; instead of making a new unit for every multiplication by ten, it would be sufficient to make one for each multiplication by one hundred, or even one thousand.

Each branch of science, trade, or business, will use the units best adapted to its particular purposes; but there is a superabundance of middle terms.

For certain special purposes, however, the smallest units we have are too large; thus it has been necessary to add a new metric unit of length for microscopical measurements (the micromillimetre); the grain is much too large as the smallest unit of weight for medicinal purposes and in analytical chemistry, the milligram being far more suitable; the cubic centimetre is too large as the smallest unit of volume in medicine, where the minim is greatly to be preferred.

Experience has shown that the use of decimal fractions is a source of frequent errors, and that in the practice of medicine and pharmacy the decimal point is dangerous, not only from want of familiarity with its right use, but chiefly because it is so often illegible, or accidentally misplaced, omitted, or duplicated. This undeniable fact must not, however, be regarded as an insurmountable obstacle to the use of the decimal *system* of weights and measures in medicine and pharmacy, but simply as an argument against the use of the decimal *point*. Use the smallest units and write whole numbers instead of fractions. In constructing prescriptions it is better to write "15 milligrams" than to write "0.015 Gm."

No decimal fractions were formerly used in writing prescriptions, because the grain was a small enough unit so long as alkaloids and other extremely potent remedies were unknown; and later, whenever the quantity required was less than a grain, *common fractions* were used to express it.

Weighing and Measuring.—When the greatest possible accuracy is required, as in some of the operations of physicists and chemists, matter is measured as to its amount by weight rather than by volume, because a given weight of any substance always expresses the same amount without regard to temperature, and because volumes cannot be easily measured with great exactness. In laboratory work, weighing is generally both convenient and accurate; but volumetric analysis is also convenient, and affords correct results.

Medicines are either solid or liquid. The liquid medicines are necessarily taken or administered in doses by measure. Hence they should also be prescribed by measure, and that is the uniform practice in the English-speaking countries. This practice is consistent, accurate, and convenient. In other countries, however, the liquid medicines are prescribed by weight, although the doses can, of course, not be apportioned otherwise than by measure. This is not only inconsistent, but gives very inaccurate results, for the prescriber cannot express definite volumes by weight, nor can he calculate the volume of a mixture composed by weight.

The practice of prescribing, dispensing, and administering liquid medicine by volume is dictated by common sense, and its results are the most accurate that can be obtained.

Many advocates of the metric system seem to labor under the mistaken idea that metric prescriptions cannot or ought not to be written, except exclusively by weight; and, on the other hand, a number of those who do write prescriptions expressing all quantities in grams, actually intend that the liquids so prescribed shall be measured, writing grams when they really mean as many cubic centimetres, overlooking or ignoring the different densities of different liquids.

Specific Weight and Specific Volume.—The relation of the weight of a mass to its volume is called its specific weight; the specific weights of solids and liquids are expressed in water units, and of gases in hydrogen units. Thus, the specific weight of water being 1,000, the specific weight of any solid or liquid is found by dividing the weight of a given volume of it by the weight of the same volume of water. Specific weight is commonly, though inaccurately, called "specific gravity," and the number used to express the specific gravity of a solid or liquid, is that number which expresses how many times the weight of that liquid contains the weight of an equal volume of water. The specific weight of ether is called 0.750, because it weighs 0.750 times as much as an equal volume of water weighs. This mode of expression is the most convenient form in which the relative weights of equal volumes of various solids and liquids can be stated and compared.

To physicians and pharmacists, the reciprocal relations of weight and volume are of great practical importance. The abolition of the use of measures of capacity in the pharmacopœial formulas for tinctures, syrups, and other liquid preparations, in the last revision, further increases the importance of the subject. It has become especially desirable to have some convenient means of expressing and comparing the relative volumes of equal weights of different liquids, and of computing readily the volume of any definite amount by weight. For this purpose the writer of this article proposed, in 1883,* to use the term "specific volume" to designate the comparative volumes of liquids, and to express their specific volumes in the same manner as their specific weights are expressed, namely, in water units. Thus the specific volume of ether is 1.333, because a given quantity by weight of ether is 1.333 times as bulky as an equal quantity by weight of water. The specific volume of any substance is obtained by dividing one by its specific weight.

$$\frac{1}{\text{sp. w.}} = \text{sp. vol.}$$

To find the volume of any number of grams of any liquid, multiply by the specific volume; the product is the answer expressed in cubic centimetres.

The utility of a table of specific volumes will be readily appreciated, and such a table should be contained in the Pharmacopœia.

As the volume of any substance is affected by heat, the specific weights and specific volumes must be ascertained and expressed at definite temperatures. The water generally taken as a standard or unit of comparison is water at 4° C. (39.2° F.), at which temperature it reaches its maximum density; but many of the pycnometers, hydrometers, and other instruments used for taking specific weight, are adjusted with reference to water at 15° C. or at 15.6° C. as unit. At the same time, the standard temperature at which specific weights are taken, and to which our "tables of specific gravities" refer, is usually 15° C., but sometimes 15.56° C., 16.67° C., 14° C., and other temperatures. This is confusing. The standard temperatures to which our instruments are adjusted, the temperature which a liquid is assumed to have when its specific weight is taken, or at which it has the specific weight given for it, and the temperature of the water referred to as unit—all should be the same temperature. The writer has recommended for this purpose the temperature of 22° C. (71.6° F.), because that is slightly above the common room temperature at which we do our work, and therefore most convenient, as well as most useful and real under ordinary conditions.

Every volume unit of the metric system has a parallel weight unit, with which it is commensurate when referring to water. Thus:

1 litre of water weighs 1 kilogram.
1 decilitre of water weighs 1 hektogram.
1 centilitre of water weighs 1 dekagram.
1 millilitre of water weighs 1 gram.

This close relationship between the units of weight and of volume is of the greatest practical value. It enables us to find the weight of any volume of any liquid by simply multiplying the volume units by the specific weight, or to find the volume of any given weight of any liquid, by multiplying the weight units by the specific volume. The weight of one litre of any liquid, expressed in kilograms (or the weight of 1 c.c. expressed in grams), is the number expressing its specific weight. The volume of 1 kgm. of any liquid, expressed in litres (or the volume of 1 gm. expressed in cubic centimetres), is the number expressing its specific volume. Conversely, the number which expresses the specific weight is the weight of one litre in kilograms (or the weight of 1 c.c. in grams), and the number which expresses the specific volume is the volume of 1 kgm. expressed in litres, or of 1 gm. in cubic centimetres.

---

* See Proceedings of the American Pharmaceutical Association, 1883.

Commensurate units of weight and volume do not exst in any other system of weights and measures except he metric system and the British Imperial system. The British Imperial system, however, has only one pair of ommensurate units—the fluidounce and the ounce—one fluidounce of water at 62° F. weighing one avoirdupois unce. But it happens that six winepints of water at 0° F. weigh 100.0032 avoirdupois ounces, or only 1.4 rains more than 100 avoirdupois ounces, and hence we an most readily find the weight (in avoirdupois ounces) f six winepints or 96 United States apothecaries' fluidunces of any liquid, by multiplying its specific weight y one hundred, the answer being sufficiently accurate r nearly all purposes.

Weights and Measures in Prescriptions.—In writing prescriptions all solid substances are prescribed by weight, and all liquids by measure, and when solids and quids are combined to form a liquid product, it is best, ecause most accurate, to adjust the total quantity to ome definite volume. Thus, if a solution be prescribed ontaining corrosive chloride of mercury, potassium dide, syrup, and water, it is, of course, impracticable or the prescriber to predict or calculate what will be the olume of the finished solution if he prescribes a given mount by weight or volume of the syrup and water; e only correct method in such a case is to prescribe ater "q.s." to make a stated volume of finished soluon.

When the old system of weights and measures is used, e most useful weight units are the grain and the ounce; ut the drachm is also convenient and very much used. he scruple ought not to be used, because the sign mployed to indicate it looks too nearly like the sign for e drachm. There ought to be a new unit of weight maller than the grain, for prescribing and stating the ses of remedies intended to be administered in minute antities, the new unit to be about gr. $\frac{1}{64}$, which is out 1 mgm. The units of capacity are the fluidounce, e fluidrachm, and the minim.

In writing prescriptions in which the quantities are pressed in units of the old system, these units are repsented by certain universally recognized signs or abeviations; the abbreviation "gr." (which should ways be written with a *small* initial) denotes grain or ains, "ʒ" denotes drachm or drachms; "℥" denotes nce or ounces; "℈" denotes scruple or scruples; "♏" notes minim or minims; "fʒ" denotes fluidrachm or idrachms; and "f℥" denotes fluidounce or fluidnces. The quantities directed to be taken are here to indicated by *Roman* numerals, always placed *after* the ns or abbreviations, as follows: gr. x.; ʒ ij.; ℥ ss.; ij; ♏ ix.; fʒ iij.; f℥ xij. The sign "ss." is used to press one-half, being an abbreviation of the Latin word *is.*

When the metric units are employed in writing a preiption, it would save human lives to abstain from ng the decimal point, and to use no other units but gram and milligram for weights, and the fluigram or he centimetre for measures. The gram is abbreviated "Gm.," a *capital* initial always being used; the milliam should be abbreviated to mGm; and the fluigram fGm (or the cubic centimetre, which is the same as a igram, to C.c.). The numerals indicating the number weight units or volume units to be taken, should be ays placed *before* the signs or abbreviations repreting the units, and in writing them the *common* (or abic) numerals should be used, thus: 10 Gm.; 50 Gm.; 30 fGm. (or 30 C.c.).

When quantities expressed in units of one system are be transposed into their corresponding equivalents in units of the other system, the following equivalents are sufficiently accurate and the most useful:

$\frac{1}{64}$ grain is equal to 1 mGm.
1 grain " " 64 mGm.
1 drachm " " 4 Gm.
1 ounce " " 32 Gm.

1 Gm. is equal to 16 grains.

1 minim is equal to $\frac{1}{16}$ fGm.
1 fluidrachm " 4 fGm.
1 fluidounce " 32 fGm.

1 fGm. is equal to 16 minims.

For further information concerning weights and measures, the reader is referred to the "Manual of Weights and Measures" by the writer of this article; Lowis A. Jackson's Work (London); "The Metric System," by F. A. P. Barnard; the Reports of Thomas Jefferson ("Works of Thomas Jefferson," vol. vii., pp. 472–495) and John Quincy Adams (Washington, 1821); the paper of Alfred B. Taylor on "Octonary Numeration and Its Application to a System of Weights and Measures," read before the American Philosophical Society, October 21st, 1887; and the Report of the Committee on Coinage, Weights, and Measures of the House of Representatives, January 7th, 1879 (45th Congress, 3d Session, H. R. Report, No. 53).

Oscar Oldberg.

WEIL'S DISEASE.—An acute infectious (?) disease characterized by sudden onset with severe symptoms, prostration, a typical temperature, early-occurring jaundice, enlargement of liver and spleen, gastro-intestinal disturbances, and nephritis.

Though first described by Weil in 1886, and taken by him from amongst the diseases characterized by and associated with jaundice, the disease had been previously noted and described under various names: "Typhus hépatique bénin," "bilious typhoid," etc. After his first description it was seen that the disease had prevailed and was prevailing sporadically and not infrequently in the countries of Europe. No distinct descriptions of its occurrence in America are met with. There seems no doubt at present that the affection is distinct from such infections as typhoid, yellow fever, recurrent fever, diseases with which it was frequently confounded; its differentiation from acute yellow atrophy, simple infectious jaundice, and various intoxications is not so clear. Accurate post-mortem reports are few, owing to the benign character of the disease. Recent bacteriological investigations are not convincing.

Etiology.—Incidence of season, sex, age, and occupation. The majority of cases are met with in the warm months of the year, June to September. Ninety per cent. of those affected are men, usually at about the age of twenty-five to thirty years (third decade). Butchers, meat handlers, sewer and drain workers seem especially prone to infection. Outbreaks in garrisons and prisons occur not infrequently.

Specific Cause.—Although recognized by many as a morbid entity, and though a seemingly definite infection or intoxication, the question as to the specific cause of the disease is most unsettled. The abrupt onset without prodromal symptoms, the occurrence of some cases within a few hours of the ingestion of noxious material, sewer gas, sewage, tainted foods, etc., before bacteria could possibly have developed sufficiently to cause an infection, suggest strongly a ptomaïn poisoning or intoxication. One very typical case followed an overdose of santonin.

The febrile course; the peculiar febrile relapse occasionally seen; the inflammatory complications described in some instances—iridocyclitis, parotitis, adenitis, pleuritis, pneumonia—are more suggestive of a bacterial or infectious agent.

Infection is evidently through the alimentary canal, although it is not easy in some epidemics to exclude the possibility of entrance through the respiratory tract; the present-day theory, however, of insect transportation of infectious material is readily applicable in this connection. The occurrence of several cases at any one time is probably due to exposure of all to the same infecting agent, rather than to infection of man from man. The frequent reports of epidemics among residents of garrisons and prisons after bathing in contaminated streams, after working in privies and sewers, or after living in unhygienic surroundings, seem confirmative of this idea.

Jaeger, Conradi, Vogt, *et al.*, have isolated a variety of proteus bacillus (B. proteus flavescens) from the urine and stools of four cases. No positive results have been obtained from the very few blood cultures made so far, and one must hesitate to accept the idea of a proteus infection being the constant cause. As in pneumonia, meningitis, and other infections there may be a variety of organisms capable of producing similar changes and symptoms. A variety of toxins or ptomaïns may, like phosphorus, exert a special influence upon the liver substance.

It is possible that the infecting substance enters the biliary system and liver directly from the intestine, being helped on its way by violent intestinal contraction. Further irritation by pancreatic secretion is a possibility under these conditions. In view of the fact that the symptoms appear simultaneously, it seems more probable that the infection starts from the intestines and is generalized by the blood. The relapse, as probably is the case in typhoid, may be due to reinfection from the gall-bladder.

PATHOLOGICAL ANATOMY.—We have no recent descriptions of the post-mortem findings. The disease is rarely fatal. Auffrecht designated his cases as "acute parenchymatous disease," finding only "granular degeneration and cloudy swelling of cells of liver, kidney, and spleen." Acute gastro-enteritis, acute nephritis, splenic hypertrophy with inflammatory infiltration, advanced destructive changes in the liver, with fatty and leucocytic infiltration, proliferation of bile capillaries resembling the early changes in acute yellow atrophy, are described. The larger bile ducts are patulous. Obstruction is due to desquamative products obstructing smaller vessels. Inflammatory lesions in other organs present nothing distinctive.

SYMPTOMS.—*General Description.*—Few diseases present a more typical course. The close similarity in all descriptions is striking. Later observers do not agree with Weil in considering the relapse or recrudescence of symptoms frequently seen a necessary characteristic. No prodromal symptoms are recorded or seem to exist. The suddenness of onset is one of the most important features of the disease. The majority of collected cases give a history of sudden collapse, while the patient is at work or on duty in apparent good health. A chill is frequent, severe headache, unconsciousness, delirium, prostration, vomiting, diarrhœa, abdominal pain are all present at the onset. Severe pain in the muscles of the legs is an almost constant symptom. Fever probably exists from the first, reaching 103°–105° F. By the second day all symptoms are exaggerated; by the third or fourth day jaundice, more or less intense, is already present; enlargement of liver and spleen, and albuminuria have appeared. The fever remains high, with slight morning remissions. The disease is at its height by the third or fourth day. From the fifth to the eighth day improvement takes place, the temperature falling by lysis, the hepatic and splenic enlargement diminishes, the albumin in the urine becomes quickly less, the nervous and other symptoms rapidly disappear. In Weil's four cases, after a fever-free interval of from one to seven days, a recrudescence of fever, lasting five or six days, took place, the other symptoms not, however, returning. As mentioned above, other observers do not consider this recrudescence an absolute characteristic of the disease. Convalescence is slow, lasting for from four to ten weeks. Traces of jaundice remain for days or weeks after the acute symptoms have subsided.

Analysis of Symptoms.—Complications.—Onset: The characteristic suddenness of onset is practically never missed. The majority of those affected are in bed by the second day of illness.

Temperature: The rapid rise has been noted. Occasionally a distinct fall takes place on the second day, only to be followed by an immediate rise to the maximum temperature, which is usually observed between the second and fourth days. A morning remission is early seen. The average duration of fever is from six to ten days, the fall to normal taking place by lysis; 106° F. may be given as the maximum, 103° F. as the average temperature. In thirty-seven per cent. of cases the recrudescence, or, better, relapse, is observed. Unlike the fever of onset that of the relapse is characterized by a gradual rise, rarely reaching the height of the first. The most common time of the relapse is from one to eight days after normal temperature has been reached. Cases with relapses as late as from the eleventh to the fourteenth day of apyrexia have been observed. The average duration of the relapse is five or six days.

Jaundice: Jaundice is of course always present. It is rarely seen before the second day, and is as a rule distinct by the third or the fifth day. It is usually well marked, but rarely as intense as in marked cases of obstructive jaundice. By from the ninth to the thirteenth day it may have disappeared. Traces persist, however, for several weeks. Increase of the jaundice during the relapse is rare. Bile-stained urine, colorless fæces are seen in the first few days, but as the obstruction of the bile flow is not complete and not in the main ducts, these characteristics are not extreme or long persistent. Itching is rather infrequent.

Condition of Liver, Spleen, and Kidneys: A recognizable enlargement of the liver is *not* a constant feature; it probably occurs in fifty per cent. of cases. When present it appears with the jaundice, usually at the fourth day. Reduction in size takes place with the lytic course of the fever. Re-enlargement during relapse is distinctly uncommon. Tenderness of the swollen liver is often noted.

In seventy-five per cent. of cases the spleen is noticeably enlarged, and can be readily palpated by the fourth day. The growth of the splenic tumor is rapid. Its shrinkage with the fall of fever is equally quick. Re-enlargement with relapse is more common than is the case with the liver. Marked albuminuria (acute nephritis) is present in about fifty-two per cent. of cases. The albumin is often excessive. Oliguria is a regular, anuria an occasional condition. Œdema is recorded but once in the cases collected. Casts and red blood cells are present in abundance. Bile reaction is marked. Distinct symptoms of uræmia are unusual. The renal condition clears up rapidly with the disappearance of the other symptoms. It may reappear with relapse. Traces of albumin, etc., can always be detected in the remaining percentage of cases. A polyuria during convalescence is usual. Hemorrhage from the bladder has been observed.

The gastro-intestinal tract is always disturbed. Vomiting is a frequent early symptom; diarrhœa an almost constant one. Distinct gastro-enteritis probably always occurs. Bloody stools are recorded. Symptoms of gastro-enteric disturbance quickly subside, and do not reappear with a relapse. The color of the stools has been noted.

The pulse keeps pace with the fever in the early days. Distinct slowing of heart's action takes place as apyrexia is approached. Endocardial murmurs are mentioned. The nervous symptoms described are those common to severe infections: delirium, convulsions, jactitations; they may outlast the fever, but are not observed in the relapse. Peripheral neuritis, hemiplegia, ophthalmoplegia have been seen toward the end of the acute symptoms.

Pains in the calves of the legs, present in half of the cases, may be neurotic or neuromuscular.

Intense prostration and slowness of convalescence are characteristic features of the disease.

Iridocyclitis as a late complication has been twice observed; retinal hemorrhage once.

Parotitis is a more frequent complication. In one instance it was double and suppurative.

Pneumonia and bronchopneumonia occur; a bronchitis at the onset is quite frequently seen. Pleurisy and pericarditis have been found in one fatal case.

Bleeding from the nose, apparently as a late symptom, seems a not unusual event.

In addition to the jaundice the skin in many instances has shown macular roseola-like rashes and petechiæ. Herpes labialis is an occasional feature.

DIAGNOSIS.—The disease is no longer confused with yellow fever, recurrent fever, or malaria. It is evidently distinct from typhoid fever. Abortive typhoid fever, as some have classed the disease, never shows the severe regular symptoms of Weil's disease. Early jaundice in typhoid fever is rare, and then only in severe cases. The Widal reaction may be utilized as a means of confirming the diagnosis. Many of the reported cases give a history of previous typhoid infection; none of the autopsied cases have shown typhoid lesions.

Epidemic jaundice, and jaundice with fever, are probably closely related to Weil's disease, which may be described merely as a more intense acute condition. Some observers consider simple jaundice the result of an infection. Enlarged liver and spleen, albuminuria and fever, though slight, can usually be found in these cases.

Acute yellow atrophy with its prodromal symptoms, lack of fever, longer duration, reduction of liver volume, and fatal ending, seems a different condition. Weil's disease may, however, be related thereto. The pathological changes of the latter disease show much more distinctive conditions. Prognosis is favorable when once the diagnosis has been clearly established.

TREATMENT is purely symptomatic and needs no discussion. *Norman B. Gwyn.*

WEST BADEN SPRINGS.—Orange County, Indiana.

POST-OFFICE.—West Baden Hotel.

ACCESS.—Viâ Ohio and Mississippi Railroad to Shoals, thence by stage or viâ Louisville, New Albany, and Chicago Railroad to Orleans, fifty-six miles north of New Albany, thence by stage to springs. These springs are located in a fine agricultural section, only one mile from the French Lick Springs. The following analysis was made by E. T. Cox, analyst:

One United States gallon of Spring No. 5 contains (solids): Sodium carbonate, gr. 9.69; magnesium carbonate, gr. 6.05; calcium carbonate, gr. 18.62; iron carbonate and aluminum carbonate, gr. 3; sodium sulphate, gr. 31.87; magnesium sulphate, gr. 27.80; calcium sulphate, gr. 108.39; sodium chloride, gr. 81.12; potassium chloride, gr. 6.13; magnesium chloride, gr. 9.20. Total, 301.87 grains. Gases: Carbonic acid, 9.26 cub. in.; sulphureted hydrogen, 2.08 cub. in.; oxygen, 5.28 cub. in.; nitrogen, 15.97 cub. in. The water is used commercially. *James K. Crook.*

WESTPHAL'S SYMPTOM. See *Knee-Jerk.*

WEST SPRINGS.—Union County, South Carolina.

POST-OFFICE.—West Springs. Hotel and cottages.

ACCESS.—From Spartanburg viâ Glenn Springs Railroad, twelve miles southeast to Glenn Springs, thence four miles southeast to West Springs. West Springs are located about 2,000 feet above the sea-level, and are surrounded by picturesque hills covered by extensive forests of spruce, pine, cottonwood, beech, oak, and other trees. The soil is very fertile and many varieties of fruits and vegetables grow in great profusion. Several gold mines are in operation among the near-by hills. There are several springs in the neighborhood, but only one is in use. It yields about four hundred gallons of water per hour. The temperature of this water is 62° F. According to an analysis made in 1893 by M. B. Hardin, analytical chemist, one United States gallon of the water contains (solids): Calcium sulphate, gr. 16.26; potassium sulphate, gr. 1.33; sodium sulphate, gr. 2.75; calcium carbonate, gr. 6.35; magnesium carbonate, gr. 1.17; sodium chloride, gr. 0.21; iron sesquioxide and alumina, gr. 0.03; silica, gr. 2.78; organic matter, a trace. Total, 30.88 grains.

The water is used considerably by South Carolina physicians in diarrhœa and dyspeptic troubles. It is said to possess excellent virtues in chronic catarrhal conditions of the genito-urinary tract—*i.e.*, in gonorrhœa, gleet, leucorrhœa, etc. *James K. Crook.*

WETEMIS MINERAL SPRINGS.—Klickitat County, Washington.

POST-OFFICE.—Blockhouse.

ACCESS.—From The Dalles, Oregon, thirty-five miles by wagon road: also from Goldendale, Washington, eighteen miles distant, by private conveyance.

These springs are new to the public, and no hotel or other accommodations for visitors have yet been provided. Those who visit them during the season, from May 1st to October 15th, are content to enjoy the pleasures of camp life, as excellent grounds for this purpose are at hand. The elevation of the location is 500 or 600 feet above the sea-level, but only a few feet above the Klickitat River, which at this point flows through a grand and picturesque canyon, a thousand feet below the level of the surrounding country. From the brink of the canyon on either side stretches a rolling plateau covered with magnificent forests of pine and fir. A few miles to the southwest lies the wheat-growing region of the Klickitat River, while less than thirty miles north Mount Adams, the second highest peak of the Cascade Range, raises its lofty summit to an elevation of 12,424 feet. The canyon of the Klickitat shelters the springs from the cold winds, while during the summer months clear, warm weather prevails, with occasional rains. The temperature seldom falls lower than —10° or —12° F., while during some winters it does not even reach the zero point. There are three large springs here and several smaller ones, but the water has never yet been analyzed. We are informed that most persons suffering from rheumatism and diseases of the stomach, who have visited the springs, have been much benefited by the water, and some of them apparently cured. Cases of phthisis do well in the neighborhood. Fine hunting and fishing may be enjoyed in the vicinity. It is probable that the spring will soon be developed. *James K. Crook.*

WET-NURSES.—At the present day the wet-nurse is by no means the absolute necessity she was in many cases before artificial feeding had reached its present stage of scientific development, so that Holt says that "when one begins with healthy digestive organs, artificial feeding is very simple and almost invariably successful." He refers to the difficulty of securing a suitable wet-nurse and the expense, from $20 to $35 a month in New York, while conceding that she may be essential in certain emergencies, such as acute inanition or acute gastro-enteric intoxication, and that she should be employed in foundling asylums whenever possible. A practitioner may therefore at any time have to decide whether he shall recommend a wet-nurse for a certain infant, and if he decides that question affirmatively he will probably have to determine how to get one, and then to pass on her qualifications for that duty. The physician who wishes to decide this question correctly must approach it from the proper point of view and study it, as he should his obstetrics, from the direction of anatomy and physiology. He will then be firmly impressed with the sound doctrine that, as a rule, maternal nursing is best for the mother and the child. Nor should he forget this fundamental principle, although his decision in the individual case will necessarily be influenced by the many modifying conditions which have always to be allowed weight in settling medical questions. Among these are the feelings, circumstances, and expectations of the family. Other points to be weighed in settling such a question are the residence of the parents, especially in the summer months, the time of year when the child may be expected to be undergoing dentition, its apparent vigor, and its freedom from hereditary tendency to disease; also any special peculiarities of development manifested by former children of the same parents, if known. Fortunately the structure and traditions of society in this country have not yet become so artificial that we need discuss the custom which prevails in French cities of handing over a baby to a wet-nurse in a remote country district, a practice the demoralizing results of which are traceable in the degeneration of those rural populations most noted for supplying these substitute mothers.

In considering this general subject of wet-nursing the physician may well devote some attention to those causes which, with ordinarily healthy women, especially in the upper walks of society, lead to the inability of such to nurse their babies. In general terms it may, in our own country, be attributed to the increasing artificiality of the life our women lead, and doubtless in part to the great wear and tear of existence in the climate of the United States. In saying this we do not overlook the fact that a more healthful and rational mode of life for the young has been coming into vogue of late. There is, doubtless, a great improvement in the matters of exercise, dress, and food over those which were usual in this country forty or fifty years ago; but the results of such changes must be slow in their development. The great stress and strain are the result of the multitudinous anxieties, cares, and ambitions which are constantly wearing upon the woman of to-day, and of the struggle for improved social position and for wealth, which bore much less heavily upon our grandmothers. Another cause, which it is not easy to estimate correctly, but which is undoubtedly influential, is the want of homogeneity in our people, and the fact that, owing to our migratory national habits, so many are constantly changing their abodes in a country possessed of such a variety of climates, that the race, blended as it is of many nationalities, has in comparatively few parts become identified with its environment. What physician but has been cognizant of many cases in which menstruation has been interrupted in healthy young women for months after immigration? If a change of climate and an unsettling of the mode of life can effect such an alteration in one phase of the generative function, why should they not be powerful in interfering with another phase of it, viz., in causing a diminished activity of the mammary glands?

Having given due weight to the considerations suggested, the medical man, before looking up a wet-nurse for his patient, may well fortify himself by a few thoughts on the objections to wet-nursing, and the very serious dangers it involves. I propose in this place to do no more than call attention briefly to the more prominent of them, trusting that they will be sufficiently brought out incidentally in treating of the different branches of the subject. There is, then, primarily the moral hazard to both mothers, for neither can fully escape the consciousness that her child is deprived of its natural right. Then note the loss to the employing mother of the stimulus of nursing in securing full and healthy involution of the uterus, and consequent freedom from disease of the pelvic organs; also the degree of immunity furnished by maternal nursing against undue frequency of conception and childbearing. On the side of the nurse it is to be remembered that her milk may prove unhealthy for her foster-child, even though it may respond satisfactorily to all the artificial tests we can apply; that grief or fierce passions may make it for the time dangerous to the nursling. Even with the greatest care in choosing them, it is almost impossible to avoid the selection of nurses who are the subjects of syphilis or tuberculous disease. And, finally, the physician and the mother can never be too watchful against the baleful effects springing from the secret use of alcoholic stimulants and of opiates.

Among the risks attending the procuring of a wet-nurse are those due to the irresponsible and mercenary character of the agencies from which they are often obtained. I think it may safely be said that the most desirable women are not to be found in these places; but that, in New York City, one of the two following plans is preferable for securing one: An advertisement in one of the daily papers will commonly bring to the door a superabundance of applicants, of whom a few selected by the family may be asked for references and handed over for medical examination. Or, secondly, inquiry may be made at one or more of the public hospitals or special charitable institutions that maintain a lying-in service, with the great incidental advantage that some accurate account of the nurse's medical history, at least during the puerperal period, can usually be had from the medical officers.

It is undeniable that under some circumstances the employment of a wet-nurse is to be recommended, and it is equally true that this advice is often given under the influence of considerations quite other than simply what would be most beneficial to the mother, the infant, or even the proposed nurse. The doctor should realize that, in order to nurse her baby, a mother must restrict herself in many ways, must be regular in her hours, which involves the loss of many pleasures which women covet, must in fact sacrifice herself for her child. Nursing, when undertaken, is a duty, the demands of which are imperative and cannot be postponed with safety to either party concerned. Diet, exercise, clothing, mental and moral habits should all be subordinated to the proper discharge of this function, though fashion and social ambition are leagued in strong opposition. This is the view that the physician should uphold and encourage. He can do more than any one else in the community to foster in the mind of every woman whom he attends during pregnancy or confinement the idea that lactation is the necessary and proper complement and rounding-out for her of the great physiological cycle which begins with conception; and the woman who follows this advice and makes these sacrifices will not need a physician to point out to her the benefits which accrue to herself and her offspring, physically, mentally, and morally, from the course adopted.

The conditions which preclude maternal nursing are briefly summed up by Lusk, as follows: "Nursing may be rendered impossible by a lack of milk, by flattened, misshapen nipples, and by the health of the mother. It should be prohibited in phthisis, in epilepsy, and in cases of syphilis contracted shortly before the birth of the child."[1] Bumm says that from fifteen to twenty per cent. of mothers cannot nurse their children.

It is well for the physician to appreciate the influence exerted by the monthly nurse, who should in this matter be his ally, and not, as is too often the case, the wily and underhanded opponent of his best efforts to make his patient nurse her babe. So potent is this influence that certain of these women come to be known as always having their charges nurse their infants, and others as always finding that they cannot do so, a reputation which may well guide the physician in passing on their qualifications.

If such care of herself as I have indicated is to be expected in the case of a mother nursing her own child, let us now apply the rule inversely and see what we should look for in a woman who is proposed as nurse to another's child, and what rules should be laid down for her guidance when acting as wet-nurse.

One of the first questions to be decided is whether we should refuse our recommendation to an unmarried woman, who may prove in all other respects well qualified. A great deal can be said on both sides of this question, but as it hinges largely upon the moral point involved, my own view is that, in so far, it is one the decision of which should not be thrown upon the medical man. The mother, or female head of the family in which the wet-nurse is to serve, would never consent to surrender her convictions on such a point, nor would a prudent physician care to assume the responsibility of introducing such a woman in opposition to the ideas of the family. Still he may be asked for an opinion as to how far, or in what ways, the fact of the applicant being single would influence her desirability as a wet-nurse, and he

ould be ready to state them. We cannot be guided by
reign opinion, for we all recognize the fact that preg-
ncy in the unmarried is not regarded with the same
niency here as in many parts of Europe, and that con-
quently the status and morale of such as have incurred
are relatively lowered. We therefore feel that such a
man, while an object of pity and deserving of all
aritable consideration, is not unadvisedly to be brought
o a family in a position which is regarded as superior
that of other servants, where she will come into close
ations with the children and the mother, and where
akness of character and lower tone might have the
st serious results. On the other hand, where the fam-
is disposed to overlook these drawbacks, especially
ere there are no older children, or to regard the inter-
s of the nursling as paramount to, or as dominating
other considerations, it may be looked upon as a
orable feature that the unmarried wet-nurse is not
bject to the claims of a husband or a family, which are
en advanced at most inconvenient seasons, and with
palpable design of profiting by the necessities of the
ployer; also that, except in the case of the very de-
aved, lactation is less likely than in the married to be
errupted by a recurrence of pregnancy. In the un-
rried there would, besides, usually be such advan-
es as accrue from the engagement of a primipara.

The age of a wet-nurse is not immaterial, and, while
unmindful of recorded facts, or those known to indi-
lual experience, where young girls or women advanced
life have proved excellent nurses, it still remains a
e rule to avoid the extremes of the child-bearing period
l to give the preference to those between twenty and
rty, or, possibly, thirty-five years. This would be, of
urse, with the view of avoiding immaturity and consti-
ional vices of tardy development on the one hand,
l, on the other, the disabilities connected with physi-
exhaustion or possible degeneration.

he age of the milk should bear some relation to the
of the child to be nursed, for, though a deficiency of
laxative qualities of the colostrum may be made good
suitable medicines, there is always danger, if the milk
uch older than the child, that the supply may not last
ong as desired. On the other hand, the quality of the
retion is, after the first few weeks, comparatively uni-
n for months, so that it will be little likely to disagree
that account even when the child is older.

s between a primipara and pluripara, other things
ng equal, the choice would be in favor of the latter,
the reason that her previous experience should have
ght her something about the proper care of an infant,
some estimate might likewise be made of the prob-
continuance of the milk supply in her case.

e now come to the physical examination of the pro-
ed wet-nurse. The physician should make this as
rough as he has opportunity for, although he will sel-
in private practice be able to complete it by ex-
ning the genitals. Still, if the woman has been con-
d in a hospital, valuable information on this point
be obtained from the house physician. A general
ey of the applicant's physique, expression, cleanli-
s, etc., should be followed by special observation of
temperature, eyes, teeth, tongue, breath, fauces, skin
pecially on the neck and breasts; also of the lungs
heart and the lymphatic glands of the neck and at
bend of the elbow. One should try to ascertain
ther pregnancy does or does not exist, and the in-
y should be made whether menstruation has taken
e, albeit the latter question may often not elicit a
hful answer and the fact will have to be learned by
equent careful observation. It is especially impor-
to ascertain the presence or absence of indications
ny form of tuberculosis, of anæmia, or of syphilis.
umatism also must not be forgotten. The breasts
uld receive special attention; they should be full and
three hours after nursing (Holt). The size and
ness of the mammary glands themselves should be
nguished from accompanying adipose deposits; the
should show the course of the large veins running from the areolæ, and it should be free from cicatrices or discolorations pointing to former abscesses or eruptions; the nipples should be of good size and prominence, without evidence of irritability or of loss of substance from former ulceration. Pressure should cause the milk to flow readily in numerous jets. A specimen of it should be obtained for chemical and microscopical examination, and, finally, the woman's own child, if nursed by herself alone, should be seen and carefully examined. Nothing can be better evidence of the value of the mother as a nurse than the condition of her own child; but it behooves the physician to be on the watch for substitution and other deceitful practices. Should it be possible, let him watch the child nurse. Then he can learn whether the milk flows easily and in abundance with but moderate effort on its part, and whether the child lets go of the nipple with an air of comfort, its lips dripping with the over-abundance of milk, or whether it repeatedly rejects the nipple unsatisfied and disappointed.

The milk itself should, of course, be examined as to both its physical and its chemical qualities. As to the former, Eustace Smith writes as follows: "The milk should be opaque and of a dull white color; under the microscope it should present fat globules of medium size, not too small. As a rule, the number of fat globules is a rough indication of the quantity of casein and sugar, though not always a trustworthy guide."[1] A more systematic and thorough method is quoted by Jacobi from F. Conrad (Bern, 1880). He draws the milk himself two or three hours after the last nursing, making use either of the breast-pump or of pressure by the thumb and index finger. This latter manipulation, after a little practice, causes no pain and makes it possible to appreciate the abundance and easy discharge of the secretion. He then determines: (1) The reaction, which should always be alkaline. (2) The specific gravity, which should be from 1.025 to 1.035; with an average of 1.031. (3) The microscopical appearance. The milk globules should be well formed, separate from each other, from 0.0088 mm. to 0.198 mm. in size, and those of medium size should predominate.[2]

Bumm quotes J. Koenig's recent analyses as showing the following chemical constitution: Sugar of milk, 6.21; milk fat, 3.78; albumin and casein, 2.29; salts, 0.71.

A wet-nurse having been chosen and her milk found to agree with her foster-child, the interests of all require that her mode of life should be so ordered as to keep her in the best condition for discharging this function. The error most likely to be committed is in changing too much her diet and régime, partly because the employers do not realize how the way of life and the kind of food to which she has been accustomed differ from their own, and partly because the nurse, finding food and other comforts in kind and quantity far exceeding those of her own home, and having withal a hearty appetite and the plausible excuse that the baby depends upon her, overindulges herself. The not uncommon result is that she grows enormously fat and at the same time loses the power to furnish the abundant supply of good milk which constituted her value. Rotch tells us that by improper feeding the quality of the milk may be changed so as to resemble cow's more than human milk in the amount of solids. This state of things leads to an attempt, probably surreptitious, to force a greater secretion by drinking beer or other alcoholics, and the downward course is begun which is not unlikely to end in the discharge of the nurse, either immediately before or after the death of the baby in convulsions. A rational management should forestall such catastrophes. In the first place, then, make the nurse bathe thoroughly and sufficiently. See that she has enough, but not too much, food of a nutritious kind and largely liquid, with an amount of exercise proportioned to her previous habits of life. Do all that is possible to secure her peace of mind and good spirits, especially by attending to the welfare of her own child, if it is living. Without going into particulars as to diet, we may say that it should be so ordered by the medical adviser as to be fully capable of replacing in the system the materials required by the secretion of milk, viz., fats and the various forms of albumin. Salts or salines should not be used largely as food or medicine, nor should articles containing strong-smelling oils. Milk is particularly good as food, while alcoholics should be avoided, unless, perhaps, a small quantity of beer for women who have always been accustomed to it in their own country.

Further details on wet-nursing may be found in the treatises on obstetrics and pediatrics. Among the works mentioned below I would call particular attention to those of Rotch and Holt. *J. Haven Emerson.*

WHANN ALKALINE LITHIA SPRINGS.—Venango County, Pennsylvania.

These springs issue from the rocky bluffs 200 feet above the Allegheny River, at a spot which commands a fine view of the charming little city of Franklin. Their high altitude and spacious woodland surroundings preclude the dangers of surface contamination. The outflow is abundant and the water clear, bright, and sparkling. Its temperature at the springs is 50° F. all the year round. The following analysis was made by Merck & Co., chemists, of New York, in 1899:

One United States gallon contains (solids): Lithium chloride, gr. 3.68; sodium chloride, gr. 3.77; calcium carbonate, gr. 3.09; magnesium carbonate, gr. 0.75; magnesium sulphate, gr. 1.17; sodium sulphate, gr. 0.16; potassium sulphate, gr. 0.30; aluminum sulphate, gr. 0.07; silica, gr. 0.69. Total solids, 13.68 grains. Total residue by evaporation, gr. 15.09; organic matter and loss on ignition, gr. 3.68; carbon dioxide, free, gr. 1.37; nitrites and nitrates, traces.

The analysis shows a light alkaline-saline water which on habitual use ought to possess useful properties as an antacid, diuretic, and possibly laxative. It has been highly praised by physicians, who have become acquainted with its use, in rheumatism, gout, dyspepsia, and gastro-intestinal disorders, and in the uric-acid diathesis. *James K. Crook.*

WHITE SULPHUR SPRINGS.—Scott County, Iowa.

Post-Office.—White Sulphur. Hotel destroyed by fire in 1893.

The waters of these springs are now used commercially. The following analysis was made by Emory Rush, of Buffalo, N. Y. One United States gallon contains (solids): Sodium chloride, gr. 92.79; calcium chloride, gr. 33.56; magnesium chloride, gr. 23.26; sodium bicarbonate, gr. 40.57; iron bicarbonate, gr. 27.37; potassium sulphate, gr. 6.13; sodium phosphate, gr. 5; silica, gr. 30.56; magnesium sulphate, gr. 16.23; carbonic acid (by weight), gr. 31.57. Total solids upon evaporation, 307.04 grains. Temperature, 56° F.

James K. Crook.

WHITE SULPHUR SPRINGS, LOUISIANA.—Catahoula Parish, Louisiana.

Post-Office.—White Sulphur Springs. Hotel.

Access.—The springs are reached by way of Alexandria, La., on the St. Louis, Iron Mountain and Southern, and the Southern Pacific Railroad, or by way of Pollock Station, on the Iron Mountain Railroad. The location is in a hilly country, covered with pines. The springs are four in number, and, according to Mr. G. W. Bethards, of the Railroad Hotel, their combined flow is about thirty thousand gallons per minute. Like many other enterprises in the South, the resort lacks capital for its improvement. No analysis has been made, but the water has been used with apparent benefit in rheumatism, dyspepsia, Bright's disease, and debility.

James K. Crook.

WHITE SULPHUR SPRINGS, MONTANA.—Meagher County, Montana.

Post-Office.—White Sulphur Springs. Hotel.

Access.—By Northern Pacific Railroad to Townsend, thence by stage or private conveyance to the springs. They may also be reached by stage from Helena, seventy-five miles distant.

The springs are located at an elevation of 5,012 feet above the sea-level, in a valley seventy-five miles long by ten or fifteen wide, watered by numerous streams where trout and other fish are abundant. Game is also plentiful in the surrounding mountains. An analysis by R. B. Riggs, of the United States Geological Survey, in 1885, showed the presence of the carbonates of sodium, calcium, and magnesium, sulphate of sodium, chlorides of sodium and potassium, silica, and a trace of sulphuretted hydrogen. The water is of the alkaline-saline-thermal type. The temperature of the water varies from 95° F. to 125° F. It is recommended for affections of the liver, for skin diseases, and for syphilis.

James K. Crook.

WHITLOW. See *Hands and Fingers, etc.*

WHOOPING-COUGH is a specific infectious disease characterized by paroxysmal attacks of coughing followed by deep inspiratory efforts, which, owing to a spasmodic contraction of the glottis, have a loud crowing or whooping sound.

Synonyms.—Whooping-cough, hooping-cough, pertussis, Keuchhusten (Ger.), coqueluche (Fr.), pertosse (Ital.), Kikhosta (Swed.), chincough, kindcough, kinkcough, kinkkaust, Kinghost, Stickhusten, Krampfhusten, Blauer-husten, Hühnerweh, Eselhusten, Rehhusten; toux convulsive ou quinteuse ou bleue, maladie cuculaire, paroxysmes quintes, architoux des enfants: tussis ferina, seu convulsiva, seu strangulans, seu quinta, seu stomachalis; anhela clamosa, seu strangulans, seu delassans, seu suffocans, seu amphemerina, seu tussiculosa, seu spasmodica, seu asinina, seu canina, seu perennis, seu clangosa, seu puerilis; tussis epidemica puerorum; bronchitis convulsiva, bronchocephalitis, pneusis pertussis; orthopnœa tussiculosa, seu clangosa, etc.; morbus cucullus, seu cucullaris; cucullus; bex convulsiva, seu theriodes; bechorthopnœa.

History.—It is generally admitted that whooping-cough was unknown to the ancients, as no description of the disease is to be found in the writings of Hippocrates, Galen, or Avicenna.

The first account we have of the disease is by Baillou or Ballonius, a Frenchman, in 1578. He called it *quintes* or *quintana*, as the paroxysms of coughing were supposed to occur at intervals of five hours. Schenck, of Grafenberg, described the disease some years later. In England there was no definite account of whooping-cough till 1667, when Willis gave a very clear description of it under the name of *tussis puerorum convulsiva;* he was followed later by the famous Sydenham. Ettmüller, in Germany, and Lieutaud, in France, also published short accounts of the disease in the seventeenth century, at which time it occurred apparently only in small epidemics, although Willis speaks of its frequent occurrence among children and of the considerable mortality caused by it.

The first entry in the London mortality returns of a death from this disease, under the name of chincough, is in the year 1668.

Throughout the eighteenth century whooping-cough rapidly increased and became widely diffused, as numerous descriptions of epidemics attest. In Sweden, from the year 1749 to the year 1764, over 43,000 children were said to have succumbed to this disease. In England, Germany, the Netherlands, Switzerland, Italy, and America, numerous epidemics prevailed.

At the present time whooping-cough not only occurs pidemically throughout Europe and America, but in nearly all the large cities and towns it has become endemic, so that cases are almost continuously occurring. In England, out of a total mortality of 510,315 in 1876, 10,556, or nearly two per cent., were due to this disease. n 1880 the proportion of deaths from whooping-cough n England was 2.59 per cent. Biermer says "whooping-cough has become a disease of all races and climates."

SYMPTOMATOLOGY.—Whooping-cough has been divided nto three stages, which are more or less distinctive in arious cases, and which pass more or less gradually rom one to the other. These are, first, the catarrhal or odromal stage; second, the paroxysmal or spasmodic tage; third, the stage of decline.

The catarrhal stage begins as a catarrh of the upper spiratory tract, and resembles an ordinary cold, from hich, indeed, it cannot as a rule be distinguished, and is often necessary to wait for the second stage before definite diagnosis can be made. The prevalence of hooping-cough in the neighborhood or the history of xposure puts the physician on his guard. The sympoms in this stage are an ordinary cough, usually rather vere, and with a tendency to become paroxysmal, ore or less coryza, with sneezing, and sometimes slight atering of the eyes, due to a mild conjunctivitis. An evation of temperature occurs in this stage, which, alough slight, is generally greater than in ordinary bronitis, and is regarded by Flint, therefore, as an idiopathic essential fever, as distinguished from a symptomatic e. Henoch, however, considers this idea of an essenl fever to be erroneous.

The duration of the first stage is generally ten days or o weeks, but it varies markedly. The younger the ild, the shorter is the first stage. Besides the factor of e, the severity of the attack also influences the duran of the prodromal stage. Thus the more severe the ack the shorter the first stage is likely to be; and, on other hand, in mild cases the first stage may be gthened to three or four weeks, or even in some cases y terminate without passing into the second stage, diagnosis in these exceptionally mild cases being de by the existence at the same time of well-marked es in other members of the same household.

The second stage, into which the first gradually or at es abruptly glides, is characterized by paroxysms of idly repeated forcible expiratory efforts or coughs, lowed by a deep inspiration, which, owing to the smodic contraction of the muscles of the larynx caus- a narrowing of the rima glottidis, has a loud and uliar crowing or whooping sound, from which the ne of the disease is derived. The little patient is genlly conscious of an impending attack, becomes rest-, and awakes from sleep, or, if at play, drops its toys h an expression of apprehension, and often appears make every effort to suppress the approaching parsm. The pulse and respirations become more rapid, when the coughing begins the child seeks to grasp mother or some firm object for support. The respiry efforts, from five to twenty in number, follow each r in rapid succession, terminating in a deep-drawn iration or whoop, and, after a rapid repetition of the es two or three times, there generally occurs the exsion of a thick, glairy, tenacious mucus, and often vomiting of the contents of the stomach, after which child sinks back exhausted, but, if in a good condi-, soon resumes its play as if nothing had happened. urine and fæces are not infrequently expelled involarily in young children, owing to the violent action of the diaphragm and abdominal muscles. Older children, who are able to describe their sensations, and adults speak of a feeling of heaviness or oppression in the chest, and of an increasing tickling sensation in the throat, or the sensation of a foreign body in that region, which lead them to expect a paroxysm. A tickling in the nose or, in some cases, the feeling of nausea is also sometimes described by the sufferers as presaging an attack. The spasm of the glottis, and therefore inspiratory whoop, is more marked when the expiratory efforts have been violent and have followed each other in rapid succession.

During the expiratory efforts the pulmonary circulation is impeded, and a backing up of blood in the right side of the heart occurs, with resulting venous stasis. The veins of the neck become distended, the face reddened, and, finally, from the interference with respiration, cyanotic. The eyes stand out and are suffused with tears, the loose connective tissue about the eyes is puffy with infiltrated serum, and in severe paroxysms hemorrhages may take place from the nose or mouth, or subconjunctival ecchymoses may appear. The tongue in infants and young children is generally violently protruded from the mouth, the frænum and lower surface scraping against the gums or teeth. The child often makes clutches at its throat and face, and endeavors to relieve itself by pulling the mucus from its mouth. In these attempts the infant, with its poorly co-ordinated movements, will sometimes scratch its neck and face, or the mucous membrane of the mouth.

After the paroxysm the cyanosis is succeeded by pallor, the distended blood-vessels empty themselves, but the puffiness about the eyes, due to the infiltrated serum, often remains as a characteristic feature. Sometimes the child is covered with a cold sweat after the paroxysm.

The duration and severity of the paroxysms may be so slight that many of these symptoms are lacking, and the expiratory efforts may be only one or two in number. On the other hand, the attack may last one or even two minutes, consisting of a number of series of expiratory efforts, causing marked cyanosis and distress, and leaving the patient in a very exhausted condition. The number of paroxysms in twenty-four hours also varies very much, from two or three in very mild cases to fifty or even a hundred in the more severe examples. A characteristic feature of whooping-cough, and one that is almost always present, is the fact that the paroxysms are more common at night than during the daytime. In the waking hours any emotional excitement is apt to bring on the cough; hence this is frequently observed during the visit of the physician. A fit of crying is almost sure to be interrupted by a paroxysm of cough, which, by substituting a greater evil, effectually removes the original cause of the tears from the mind of the little patient. In a similar way, with several children in a room all suffering from this disease, the occurrence of a paroxysm in one is apt to be followed by the same thing in the others—the so-called paroxysm from imitation.

The fever, which may have been present in the first stage, is now generally absent, although an occasional temperature of 101° or 102° F. in the evening is not at all uncommon. A continuously elevated temperature, on the other hand, would at once point to some complication.

Vomiting following the paroxysm may be so frequent as seriously to interfere with the nutrition of the patient. In these cases the stomach becomes so sensitive that a very slight cough may be followed by the evacuation of the entire contents of the stomach; whereas in earlier periods of the same case or in milder cases vomiting occurs only after violent paroxysms. The general condition of the patient during the intervals between the attacks, supposing there are no complications, remains good if the course of the disease is mild; but if severe, the patient becomes much emaciated and debilitated.

The duration of the second stage varies very much, but averages from four to eight weeks, and gradually merges into the third stage, or stage of decline, when the cough has become less frequent and has ceased to be spasmodic. This stage lasts generally two or three weeks, but is apt to be interrupted and prolonged by returns of the old paroxysmal cough. In fact, for a year or two after an attack of whooping-cough, an ordinary bronchitis is apt to take on the spasmodic character of the former disease.

When uninfluenced by treatment, therefore, whooping-cough runs a course of from two to three months. A duration of less than six weeks is uncommon, while one of more than three months is unfortunately less so. An average of ten weeks, as stated by West, is probably as accurate an estimate as can be given.

The physical examination in an interval between paroxysms of cough will show, in uncomplicated cases, more or less emaciation and anæmia dependent on the severity of the attack, possibly slight puffiness of the face, especially about the eyes, and in some cases an excoriation or ulcer on the frænum linguæ, with perhaps a slight bronchitis. In mild cases of whooping-cough there may be an entire absence of these signs, and the child may appear to be in perfect health during the intervals of the cough.

Sugar is occasionally found in the urine. Dolan found traces in fourteen out of fifty cases examined on this point. Albumin may also occasionally be found.

Complications.—The principal complications of whooping-cough may be divided into three classes: first, those due to an increase or extension of the mild inflammation of the air passages, which probably accompanies all cases of whooping-cough; secondly, complications due directly or indirectly to the paroxysm of coughing; and thirdly, accidental complications.

Bronchitis, although generally present in whooping-cough, is always, even in its mildest form, considered a complication by some authors. This bronchitis may increase and involve the smaller capillary tubes, especially in debilitated children and where the hygienic surroundings are poor, and result in bronchopneumonia. This is the most serious complication and is largely responsible for the mortality. With the presence of bronchopneumonia the little patient can ill bear the paroxysms of cough, but these fortunately, as a rule, become less severe at this time, so that false hopes are thereby excited.

Of the complications due to the violent paroxysms of cough may be mentioned pulmonary vesicular emphysema. Its diagnosis during life is often impossible, but the condition is frequently seen at post-mortem examinations, especially in the upper lobes of the lungs.

A more extreme condition rarely occurs, namely, rupture of the air cells, giving rise to interlobular emphysema. In these cases the air is sometimes forced into the loose connective tissue of the neck or even of the entire body.

According to Strümpell, a lobular emphysema may sometimes persist as a chronic state after recovery from whooping-cough.

Another group of complications that may result from violent paroxysms of coughing are hemorrhages. Epistaxis is the most frequent form, and may in some cases be so severe as greatly to enfeeble the patient or even to prove fatal. The next most common source of hemorrhage is the mouth, either from the ulcer or abrasion under the tongue, produced by friction against the lower incisors, or from the dry and cracked lips which are rubbed or picked by the little patient, or from the gums, tongue, pharynx, or indeed from any part of the buccal cavity. If stomatitis exist, the facility for bleeding is of course increased. In cases of bleeding from the mouth, the mucus, which is churned about in the mouth before it is expelled, becomes of course blood-stained, or the patient even spits out pure blood, if the hemorrhage is sufficiently free. This alarms the parents much more than a copious epistaxis would do, and they send for the doctor at once, thinking the child is coughing up blood from the lungs. True hæmoptysis, however, is very rare in children under ten years of age, and even in tuberculous cases is seldom seen at such an early age.

Subconjunctival hemorrhages are not uncommon and give no pain, neither do they interfere with vision. They are almost diagnostic of this disease, as they are rarely seen in children from other causes, trauma of course being excluded. A conjunctival hemorrhage is rare. Trousseau reports a case in which it gave the appearance of tears of blood. Vision may be partially or totally obscured by hemorrhage into the retina. Blindness in whooping-cough has been found in some cases to be due to ischæmia retinæ. Exophthalmus from hemorrhage behind the ball has been observed, also subluxation of the lens due to partial rupture of the zonula Zinnii in a fit of coughing.

Otorrhagia is very rare, and is due to the rupture of the membrana tympani by the air being violently forced up the Eustachian tube during coughing, or by the rupture of the vessels of the external auditory canal, which have been altered by an acute or chronic inflammation.

Subcutaneous hemorrhages, or ecchymoses, occasionally occur.

Hemorrhages of the brain or meninges, as is natural to infer, occur from the same causes as hemorrhages elsewhere, although they are rare and are of very serious and often fatal import. The history is usually that of a severe paroxysm of cough, followed by paralysis and loss of sensation in various parts, often a hemiplegia with unconsciousness and convulsive movements. The symptoms may gradually increase in severity, pointing to a slowly progressing hemorrhage. Very serious and ominous symptoms may be followed by complete recovery, so that the physician must not hurriedly give a fatal prognosis.

Convulsions in whooping-cough are, however, often due simply to the general reflex disturbance, owing to the high state of tension of the nervous system in children; but cerebral or spinal congestion, resulting solely from the cough, may be, and frequently is, a cause of the convulsions.

Hernia of the bowels and prolapsus ani are not infrequently seen, resulting from the strong expiratory efforts; and, rarely, the rupture of the rectus abdominis with the formation of a large tumor.

Etiology.—The infectious nature of this disease demands a living organism as the causative agent, and observers all over the world have been busy on this problem.

Deichler, in 1886, found always present in the sputa of whooping-cough patients an amœba-like protozoon. This has been confirmed more lately by Kinloff, and again by Behla, but the importance of this organism in the etiology of the disease may perhaps be doubted.

Afanassieff, in 1887, found in the sputa short, rod-like bacteria of 0.6 to 2.2 μ in size, from which he obtained pure cultures, and states that this bacillus—"Bacillus tussis convulsivæ"—is distinctive from any previously described bacterium. With the pure culture he made eighteen experiments on animals by injecting it into the trachea or lungs, by which he produced in all cases symptoms of whooping-cough. On post-mortem examination of these cases he states that these bacteria were found on the mucous membrane of the bronchi, trachea, and nose, and he also found the same germ on the mucous membrane of the respiratory passages of children who died of whooping-cough.

Since then Ritter, Zusch, Czaplewski and Hensel, and Koplik have all isolated and studied a bacillus which is perhaps identical with that first described by Afanassieff.

Czaplewski and Hensel worked out a method which did not fail to show this characteristic bacillus in every case. They described the bacillus as being oval with rounded ends, which sometimes stain more deeply than the centre, giving the appearance of a diplococcus.

Whooping-cough is contagious during its whole course, especially during the first or catarrhal stage. It is least contagious during the third stage, or stage of decline, and its contagiousness may cease while the cough, which is then due to a simple bronchitis, still continues. The contagiousness may even cease before the whooping has stopped, for this latter may be kept up simply as a nervous habit. So-called relapses, where the spasmodic attacks return during mild bronchial catarrhs acquired shortly after the whooping-cough has ceased, are generally to be explained in the same way, and are therefore not contagious. One attack of the disease secures immunity from it for the future, yet two or more distinct attacks of the disease in the same individual may sometimes, though rarely, occur.

Whooping-cough is very rarely carried by a third person or by the medium of clothing. Roger gives an instance of a boy sick for a long time with typhoid fever, never in contact with a case of whooping-cough, and yet developing that disease. The father and the doctor were the only ones who saw the patient, and therefore one of these must have acted as the medium for conveying the poison of the disease. I have recently seen a case in which the evidence of transmission by a third person was very clear. Clothing stained with sputa, it would seem, might easily convey the disease, although facts on this point are lacking. It is probable that the poison does not long survive outside of the body.

Like all contagious diseases whooping-cough prevails at times epidemically, and sporadic cases are to be traced to some previous case. Most large towns and cities are never entirely free from the contagion of this disease and cases exist at all times; or, in other words, whooping-cough is there naturalized or endemic. After a year of unusually great prevalence of whooping-cough in any large town or city, the number of cases in the following year is generally much less, a fact easily explained, as there are comparatively few children who are not protected by having suffered from the disease the year before.

The period of *incubation* varies considerably, but is generally from four to ten days in length.

Whooping-cough may occur in the new-born infant and in the aged, but is most common between the ages of one and five years.

In fact, owing to the almost universal prevalence of whooping-cough, very few children escape the disease, and this fact sufficiently accounts for its infrequency in adult life.

There are a few cases recorded in which the infant was born with the disease, the fœtus being infected in the uterus from the mother who was suffering with the disease.

As to the season of the year, one would expect to find whooping-cough more prevalent in the winter, owing to the greater chances of infection by aggregation of children in schools, and the imperfect ventilation that prevails in this season as compared with the summer. Hirsch, however, has shown that the seasons have no influence on the spread of this disease.

PATHOLOGY.—Post-mortem examinations in cases of whooping-cough almost invariably show the morbid anatomy of some complication, as death from the disease alone is almost unknown. In the latter case we would find evidence of slight catarrh of the air passages, so slight and superficial as to be scarcely noticed. Examinations during life by means of the laryngoscope give us the most satisfactory knowledge of the pathological changes, and these studies have been made by observers, partly on themselves while suffering from an attack of whooping-cough, and also on others. The most elaborate and complete observations of Meyer Hüni and von Herff are in the main similar. They found a superficial inflammation or catarrh of the mucous membrane, from the nose and pharynx to the bifurcation of the trachea. The inflammation was found most marked on the posterior wall of the larynx, on the arytenoid cartilages and those of Santorini and Wrisberg, and especially in the interarytenoid region, and also on the under surface of the epiglottis. The vocal cords were intact. The posterior wall of the larynx, as high as the vocal cords, constituted the so-called "cough region"; that is to say, irritation of this part by flecks of mucus, or artificially by a laryngeal probe, as shown by von Herff, always brought on a violent paroxysm of cough. A similar but less intense one was produced by irritating the lower surface of the epiglottis, while touching other parts of the larynx never brought on a true paroxysm. Flecks of mucus were seen by these observers to bring on a paroxysm of coughing, when they reached the opening of the glottis, which continued till they were expelled. During the violent inspirations the incoming air draws down the partially coughed-up bronchial secretion, renewing the irritation, and again bringing on a paroxysm, and the series ceases only on the complete expulsion of the mucus, or until, through exhaustion, the irritability is dulled. Meyer Hüni thinks that there is also probably another "cough region" at the bifurcation of the trachea.

Rossbach's observations, however, differ entirely from these, for he found the pharynx, larynx, and upper two-thirds of the trachea normal, without either redness or swelling of the mucous membrane. A catarrh of the larger bronchi, however, he considered a part of the disease, and just before a paroxysm he saw bubbles of mucus coming up from the lower part of the trachea.

Besides the superficial catarrh, involving more or less of the upper air passages in mild cases of whooping-cough, pathological changes are absent. The ulcer sometimes found under the tongue was at one time thought to be the specific lesion of whooping-cough, but is now recognized to be due to the friction of the tongue against the lower incisors, when it is violently thrust out in a paroxysm of coughing.

DIAGNOSIS.—During the first stage the diagnosis of whooping-cough is impossible in the majority of cases. The history of exposure to the contagion of whooping-cough, in a patient not protected by a previous attack, should make the physician suspicious of this disease when he finds a cough with few or no signs of bronchitis, especially if there be an elevation of temperaure out of proportion to the severity of the bronchitis. During the prevalence of an epidemic, all cases of cough not due to any well-recognized cause, in children unprotected by a previous attack, should always arouse the suspicions of the physician, and the possibility of the disease should be mentioned to the parents, so that they may be on the lookout for the whoop. Whooping is, indeed, the characteristic symptom of the disease, but is not heard till the second stage has been reached, and when this is well marked the diagnosis is easily made. The visit of the physician often excites the child so that a paroxysm is induced, making the diagnosis plain. Pressing on the larynx or the root of the tongue, or on the vagus nerve at the base of the neck, or making the child cry, may be resorted to for diagnostic purposes to bring on a paroxysm of coughing.

In infants under six months of age, and in very mild cases in older children, the diagnostic whoop is often absent. Here we must depend on the history of exposure to contagion, on the history of a quiescent or incubative stage, and on that of a prodromal catarrhal stage; on the paroxysmal character of the cough, generally more frequent at night; on the congestion of the face during the paroxysm, the expectoration of the characteristic glairy, tenacious mucus, and the vomiting of the contents of the stomach. Whooping-cough is, indeed, the only disease in infants in which there occurs actual expectoration of abundant mucus.

The appearance of the child in the intervals between the paroxsyms is almost diagnostic in cases in which the course of the disease is severe. In these cases we find pallor, more or less emaciation, puffiness under the eyes, congestion of the conjunctivæ, and, in a certain proportion of the cases, abrasions or ulcerations of the frænum linguæ. Subconjunctival ecchymoses in children are almost pathognomonic of whooping-cough, as they are rarely seen in them from any other cause excepting traumatism.

In many cases it is a very difficult matter to decide whether a patient has whooping-cough or merely a bronchitis with copious secretion of mucus, causing suffocative or spasmodic attacks of coughing. Here [illegible] carefully consider all the points mentioned [illegible] treat doubtful cases as cases of the disease u[illegible] nosis is clear, isolating them as much as possible, and refusing to admit them to the open wards of hospitals or other institutions.

Recently Meunier has pointed out a method for early diagnosis, namely, the constant leucocytosis which he has found in this disease, one that far exceeds the leucocytosis found in other febrile affections of the respiratory tract. The leucocytosis begins early, before the appearance of the typical paroxysms, and averages 25,000, reaching later as high as 40,000. Fröhlich found that the leucocytosis kept pace with the number of kinks. Wanstall has not confirmed these statements, he finds, however, an increased percentage of lymphocytes, at least equalling or exceeding that of the polynuclear neutrophilic cells, which he considers of diagnostic importance.

A method for certain early diagnosis of whooping-cough would be of the greatest practical service.

PROGNOSIS.—The prognosis in whooping-cough is very favorable if the general health of the patient is good and there be no complications. The occurrence of the latter, moreover, is largely dependent on the former, for the stronger the patient the less liable is he to complications, and death, in the absence of complications, rarely occurs.

Of the complications which cause death, by far the most common is lobular or broncho-pneumonia. The little patient may also die from exhaustion and malnutrition induced by the protracted course of the disease, the disturbed sleep, exhausting attacks of coughing, and starvation owing to the frequent vomiting. Hemorrhages from mucous membranes add greatly to the debility, and may in themselves prove fatal. Owing to the feeble state induced by these causes, the prognosis in intercurrent diseases is made much more unfavorable.

The prognosis in those already weakened by chronic disease or by previous acute disease is also more unfavorable; especially is this the case if the acute disease has left the bronchial mucous membrane impaired, as in the case of measles, for the patient is then more liable to complicating bronchitis which may eventuate in a severe broncho-pneumonia and death. Broncho-pneumonia is, indeed, the final act in a large proportion of the fatal cases of whooping-cough.

Convulsions are always of unfavorable import, whether they be due to the reflex irritability, to congestion and œdema of the brain, or to cerebral hemorrhage.

The age of the patient influences the prognosis very much; for the older the children the better able are they to withstand the exhausting effects of the disease, and the less liable are they to complications.

In adults the disease runs, as a rule, a moderate course, and the prognosis is good unless other unfavorable conditions exist. In the aged we again return to the feeble state similar to childhood, when resistance to disease is impaired, and here the prognosis may become unfavorable.

In Basle, according to Hagenbach, the mortality by ages, during eleven years, was as follows: Under one year, 26.8 per cent.; one to two years, 13.8 per cent.; two to five years, 3 per cent.; five to ten years, 1.8 per cent.; ten to fifteen years, 1.8 per cent. Biermer estimates that 31 per cent. of the fatal cases of whooping-cough occur in the first year of life.

As to sex, the prognosis is slightly more unfavorable for females than for males.

Dolan states that whooping-cough causes one-fourth of the annual mortality among children under five years in London.

In the United States, according to the census of 1880, the list of deaths from infectious diseases is as follows:

	Under five years.	At all ages.
Deaths from diphtheria.........	19,854	38,143
Deaths from whooping-cough...	10,313	11,064
Deaths from scarlet fever.......	10,142	16,388
Deaths from measles......	5,481	8,072

The United States census of 1880 also shows a greater proportion of deaths in the rural districts (16.9) than in the large cities (9.7), and, in the regions where a distinction of color was made, a much greater proportion among the colored (33), than among the whites (14.3).

The census also shows the largest proportion of deaths to the total mortality to occur in the Appalachian region, comprising portions of Virginia, West Virginia, Kentucky, Tennessee, and Alabama, and on the Southern Atlantic coast, from the mouth of the Chesapeake Bay to the northern boundary of Florida, including both Carolinas and Georgia. The smallest number of deaths occurred in New England, New York, and Pennsylvania, the proportion there being under ten in one thousand deaths from known causes.

According to the United States Census of 1860, 1870, and 1880, comprising 17,939 cases, the greatest mortality from whooping-cough occurred in March, April, and May, and the least in October, November, and December.

TREATMENT.—As in all diseases which are prevalent, which are obstinate to treatment, and which run a definite course and get well of themselves, there are numerous plans of treatment for whooping-cough, and numerous remedies have from time to time been recommended by different men. These remedies have had for themselves longer or shorter periods of popularity, and many are forgotten. The literature of this subject is very large. It is unfortunate that many forms of treatment are recommended and become popular on insufficient foundation—a small number of cases reported, general impressions without careful record of cases, and lastly, disregard of the fact that the disease tends to recovery untreated.

Another source of error lies in the fact that whooping-cough varies very greatly in its severity, some cases even without treatment running a mild course with but few daily paroxysms. This variability is not taken into account, and it is very rare to find it stated at what stage treatment was begun. It is evident that there is a time in every case of whooping-cough when the administration of any drug will give apparently favorable results, simply because the disease is improving of itself. This natural improvement is sometimes very rapid without any treatment.

As the disease is a long and debilitating one it is plain that all drugs that interfere with the appetite, that disturb the digestion, or that depress the heart should be carefully avoided. It is far better to depend on hygienic treatment alone than to do harm in these ways, and render the patient more liable to complications.

The patient should be placed under the most favorable hygienic conditions, particular attention being given to good ventilation when the child is in the house. In favorable weather the patient should be out of doors as much as possible, and arrangements should be made, if possible, in summer for the child to sleep either in a tent or on a piazza or balcony. The diminution in the number of paroxysms while the child is in the open air is always very marked. The bedroom windows should be widely opened, the patient protected by screens from draughts, and an open fire kept going in the room if the weather is cold.

Sea-bathing, with care and moderation, in certain cases, or salt baths in the room, are of value, if they are followed by a warm and pleasant reaction of the skin. This reaction will be aided by rubbing the skin with a coarse towel. A change from the city to the country or seashore is often useful, but the danger of imparting the disease to others, and starting an epidemic in a new place, should always be considered. A mild moist atmosphere, by acting favorably on the laryngeal and bronchial inflammation, mitigates the disease. This can be obtained artificially by means of an atomizer, steam spray, or steam kettle, or by wet cloths hung about the room.

The diet should be carefully attended to; it should be very nourishing and easily digestible, and, if there is a tendency to vomit, food should be given frequently and in small quantities. The times of feeding should be arranged with reference to the paroxysms; thus, as cough and vomiting are apt to occur in the morning on waking, it is better to wait for an hour or so till this has passed. At evening the child not infrequently has a paroxysm as soon as he is put to bed; hence, supper should be given at least an hour before bedtime, so that it will have a chance to be digested and not vomited. During the day food should be given after a paroxysm of coughing and vomiting, with the hope that it will be digested before the next attack.

The severity of the paroxysms may be mitigated by turning the child on its face with the head low, and detaching the mucus from the mouth with the finger, a practice which is commonly followed among the lower classes. The pressure of the hand over the eyes gives relief by preventing the strain upon them.

The number of drugs used is legion, and it is necessary to speak here of only the more important. Belladonna is one of the more popular antispasmodic drugs. It diminishes not only the hyperæsthesia and muscular spasm, but also the hypersecretion of mucus in the air passages. It is generally well borne by children, and should be given first in small doses, the dose being gradually increased till physiological effects appear. The medicine may then be given in smaller doses or omitted for a while. It is often given combined with the bromides.

Cocaine, from its marked local anæsthetic effect on mucous membranes, has naturally been used in the treatment of whooping-cough. It has been applied in solution by a brush to the larynx and pharynx, or sprayed into the throat by an atomizer, or by inhalation of its vapor. Cocaine should, however, be used with great caution and in very weak solution. Alarming symptoms have resulted from a few sprayings with a four-per-cent. solution in infants.

Cochineal and grindelia robusta have had reputations, and are still believed in by some. Dried chestnut leaves steeped in the form of a tea can be given safely to young children, and often appear to give surprisingly good results.

Antiseptic drugs are given internally by the mouth or rectum in whooping-cough, or applied locally by means of inhalation of atomized solutions or of gases; by applications of solutions to the pharynx, larynx, or nose, by means of brushes or swabs; by applications to the nose and pharynx by syringing; or, lastly, by the insufflation of fine powders into the nose, pharynx, or larynx.

One of the oldest forms of antiseptic treatment is the breathing of the air in the purifying room of gas-houses, a method, according to Roger, first used by Dr. Desmartes in 1859. Five or six years after this, this method became very popular, but it is at the present time but little used.

Among volatile antiseptic drugs given by inhalation may be mentioned turpentine, eucalyptus, pinus sylvestris, cresolin, thymol, and carbolic acid. These may be poured on boiling water, and the head held over the vessel, or they may be evaporated on water boiling over a lamp in a room. The objection to this method is that it is apt to interfere with free ventilation. Cases of poisoning from carbolic acid and cresolin have been reported.

Mohn has reported cases of whooping-cough cured, "as if by enchantment," by the use of sulphur fumigations. The child is dressed in clean clothes and sent from its room, which is closed and fumigated with burning sulphur for five hours in the morning. After the room is aired, the child sleeps there at night. One trial is generally sufficient for a cure. These observations have been confirmed by some and found valueless by others.

Quinine is deserving of more extended notice and its beneficial results were summed up in the Medical Congress of 1887 by Binz as follows:

First. That whooping-cough can be shortened and made mild by quinine (giving as many decigrams in twenty-four hours as the child has years).

Second. The prognosis is more favorable the earlier the treatment is begun.

Third. That the hydrochlorate of quinine given by the mouth is the best, the sulphate of quinine the next best form.

Laryngeal insufflations of quinine in the form of a fine powder were first used by Letzerich, one of the earliest investigators of the parasitic origin of whooping-cough, and the results reported by him and other observers have been very satisfactory.

Nasal insufflations of quinine have the advantage of greater simplicity of manipulation, and can easily be given by the parents—a very important consideration, for in a large class of patients daily visits of the physician in whooping-cough are out of the question. They are also less disagreeable to the patient, in fact can be given without in the least disturbing him.

Powdered benzoin, boric acid alone or mixed with roasted coffee, iodoform, tannin, and salicylic acid have also been used in nasal insufflations.

Resorcin is a drug which has been largely used by Dr. Moncorvo, of Rio Janeiro, in the treatment of this disease, and reference is here made to his important and elaborate monograph on the subject. He applies a one- or two-per-cent. aqueous solution of the drug with a brush or probang to the opening of the glottis daily, and with good results. The advantages of resorcin over many other antiseptics are its slight or agreeable taste, almost no odor, and its feeble toxic or caustic action. Moncorvo says that children object to the first application, but afterward submit with great docility.

Asaprol in a one-per-cent. solution applied to the larynx has been favorably reported, as has also a spray of peroxide of hydrogen 1 part, water 10 parts, and glycerin 1.5 parts. Menthol in liquid vaseline has also been used. The objection to all sprays and applications to the larynx is the difficulty of carrying them out in children and the liability to bring on gagging and vomiting.

Oxygen and ozone have also been used as inhalations.

Antipyrin has been used very largely in whooping-cough, notwithstanding its well-known depressant effects, and favorable results are reported by several able observers. Cases of injury from cardiac depression are also recorded, and it seems doubtful whether it is well to run the risk of the unfavorable effects of this drug.

Bromoform has been largely used of late, and appears to act better than most other drugs in diminishing the frequency and the severity of the paroxysms of whooping-cough. It should never be given in an emulsion, as, unless the bottle is thoroughly shaken, it will settle to the bottom and the last few doses cause serious or fatal results. It is best dropped on sugar, the dose being about one drop for each year of age, given every four hours.

Another still more recent drug of great value in whooping-cough is heroin. This can be given to a child three years old in doses of gr. $\frac{1}{25}$ three or four times daily, and it certainly has considerable effect in quieting the paroxysms, although in some cases it is of but little value.

Of late, various compounds with suggestive names have been used with varying success. The interpretation of these names follows:

Antitussin = difluorphenyl.

Pertussin = saccharated extract of thyme.

Antispasmin = a combination of one molecule of narcein natrium with three of salicylate of sodium.

Tussol = amygdalic acid and antipyrin.

PROPHYLAXIS.—The only means we have for the prevention of the spread of whooping-cough is isolation of the patient.

Isolation in the case of the exanthemata is easily practised on account of the short duration of these diseases, and the fact that the patient is confined to bed. In whooping-cough, however, we have a disease whose period of contagiousness may continue over two months, during which the patient is able to be about the house and go out of doors. It is a disease which is usually not recognized, and for which the physician is not called till a week or two have elapsed, during which the other members of the household, and probably of the school, are exposed to contagion. Hence isolation is rarely practised, and mothers among certain classes even adopt the pernicious practice of allowing their children to be exposed to contagion, on the ground that they must have whooping-cough some time, and the sooner they have it and are over it the better. This idea should be combated wherever found, for, as we have already seen, the older a child is the better able is he to resist the debilitating effects of the disease, while in infants the danger of a fatal result is considerable. Adults, even if not less susceptible, are less frequently exposed to whooping-cough than young children, and in them the disease generally runs a mild course. If possible, the patient should live and sleep in a room away from the other children of the family, who should not be allowed to visit him or play with him out of doors. The mother or nurse should, if possible, air or change her clothes and wash her hands on leaving the patient to go to the other children. These precautions are certainly worth while if there be a young infant in the family, or a delicate child, or one weakened by sickness.

Parents should be reminded of the evil of taking children suffering from this disease in public conveyances, or to places of public meeting, as churches, shops, where other children may be infected.

Dispensaries and out-patient departments of hospitals often serve to spread the disease, the child with whooping-cough sitting, perhaps for several hours, on benches with other children. Such cases should either be seen and sent off at once, or kept in a separate room.

It is unfortunate that whooping-cough should be especially contagious in the early stages before the diagnosis is made clear by the characteristic whoop. The contagion diminishes during the spasmodic stage and probably ceases before the child has ceased whooping.

Disinfection of the room and its contents, after death or recovery from whooping-cough, should always be practised, although, as before remarked, it is not probable that the poison survives long outside of the body.

Charles W. Townsend.

WIESEN. See *Davos.*

WILBUR SPRINGS.—Colusa County, California.

These mineral springs are located thirty miles from Colusa. They are pleasantly situated and have acquired considerable reputation. The waters are hot and sulphureted, and, according to Anderson's analysis, one United States gallon contains (solids): Sodium chloride, gr. 19.75; sodium carbonate, gr. 8.40; sodium sulphate, gr. 26.10; potassium chloride, gr. 0.46; silicates, gr. 6 95; magnesium sulphate, gr. 22.90; magnesium carbonate, gr. 5.10; calcium carbonate, gr. 8.44; calcium sulphate, gr. 20.62; ferrous sulphate, gr. 4.16; alumina, gr. 8.98; potassium iodide, gr. 0.75; organic matter, gr. 1.74. Total solids, 124.89 grains. Sulphureted hydrogen gas, 43.97 cubic inches. A hotel and cottages have been built, and there are also excellent camping facilities.

James K. Crook.

WILDEN SPRING.—Franklin County, Vermont.

Post-Office.—St. Albans. Hotel in St. Albans.

Access.—St. Albans is a prominent railroad station on the Vermont Central Railroad, in the extreme north corner of the State.

St. Albans is a delightful town overlooking Lake Champlain, two miles west. The spring is situated on Edwards Street, south of Lake Street, about ten minutes' walk west of the depot. The water was analyzed by A. A. Hayes, M.D., of Boston, who found the following chemical constituents: Sodium carbonate, magnesium carbonate, calcium carbonate, sodium chloride, potassium sulphate, calcium sulphate, magnesium iodide, iron crenate, sodium silicate. Solid constituents per United States gallon about twenty-four grains.

The water has been considerably resorted to in the past, but so far as we can learn it is not now employed for medicinal purposes. *James K. Crook.*

WILHOIT'S SODA SPRINGS.—Clackamus County, Oregon.

Post-Office.—Wilhoit. Hotel.

Access.—From Salem, Marion County, twenty-five miles northeast by wagon road.

These springs are seven in number and flow about seven hundred gallons per hour. An analysis by J. A. Veatch, M.D., in 1869, gave the following results: One United States gallon contains (solids): Sodium carbonate, gr. 87.57; magnesium carbonate, gr. 85.82; calcium carbonate, gr. 82.28; iron carbonate, gr. 6; sodium sulphate, gr. 3.40; magnesium sulphate, gr. 6.45; sodium chloride, gr. 201; iodine, a trace. Total solids, 421.97 grains. Carbonic acid gas, 22.56 cubic inches.

The water, as it flows, is said to have a temperature of 85° F. This is a very valuable water, combining as it does a number of important chemical ingredients. It is not unpleasant to the palate, and, according to Dr. H. Carpenter, it operates on the second day as a laxative and diuretic. It contains a considerable percentage of iron, which gives it tonic and reconstructive properties.

James K. Crook.

WILLOW. See *Salicaceæ.*

WINNIPEG.—This city, the capital of the province of Manitoba, is situated at the junction of the Red River of the North and the Assiniboine, 485 miles south of Lake Winnipeg and 1,424 miles west of Montreal. From the boundary of the United States it is about 60 miles north, North Dakota and Minnesota forming the southern boundary of the province. It is a city of 45,000 inhabitants, the metropolis of all this region, and is constantly growing. It is well laid out with broad streets, and has many public buildings—colleges, handsome churches, a general hospital, banks, etc. It is reached viâ the Canadian Pacific Railroad from the east, or the Northern Pacific from St. Paul.

The province of Manitoba, embracing 73,956 square miles, is a level prairie, about 800 feet above the sea-level, and contains three important lakes: Winnipeg, Manitoba, and Winnipegoosis. Like the neighboring Dakotas and Minnesota, Manitoba is noted for its wheat, which is the staple product. The rivers and lakes abound in fish, and large and small game is plentiful.

The climate of this region is healthy, but the extremes f temperature are great, as is also the annual range. he winters are long and cold. According to Hann “Handbuch der Klimatologie”) the temperature falls lmost every winter as low as 40° below zero F., while summer it may rise to 100° F. Owing to the comarative dryness of the air, however, the cold is said not be severely felt. The average annual mean temerature of Winnipeg is 33.8° F., which, according to linsdale, is lower than that of any other large city in merica.

The following table of the monthly and annual temerature and precipitation was kindly furnished by rof. R. F. Stupart, director of the Meteorological Serice, Toronto:

WINNIPEG, MANITOBA.

Table showing	Jan.	Feb.	Mar.	Apr.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.	Year.
verage mean highest temperature	5.4°	10.4°	24.6°	46.6°	65.1°	74.5°	78.3°	75.9°	64.7°	50.2°	27.8°	14.6°	78.3°
verage mean lowest temperature	−16.2	−12.6	7.4	25.3	39.0	49.7	53.8	50.5	41.0	29.8	10.0	−5.3	−16.2
verage mean monthly and annual temperature	−5.4	−1.1	16.2	36.0	52.1	62.1	66.1	63.2	52.8	39.7	18.9	4.6	33.8
verage daily range of temperature	21.6	23.0	16.7	21.3	26.1	24.8	24.5	25 4	23.7	20.9	17.8	19.9	....
bsolute highest temperature	40.0	46.0	64.0	90.0	94.0	96.0	98.0	103.0	94.0	85.0	64.0	47.0	103.0
bsolute lowest temperature	−46.0	−46.0	−38.0	−14.0	15.0	21.0	36.0	30.0	19.0	−3.0	−34.0	−53.0	−53.0
verage rainfall in inches	....	....	0.25	1.17	2.15	3.53	3.08	2.63	2.09	1.52	.17	.14	16.73
verage snowfall in inches	8.7	9.4	8.8	4.3	1.3	.3	....	....	....	1.3	9.8	7.6	51.5

The average daily maximum temperature for July is .3 F., and the minimum, 53.8° F. The annual range temperature is from 130° to 140° F. The average total nnual precipitation for Manitoba is 17.43 inches, but of is 12.87 inches falls in the six months from April 1st October 1st. The mean relative humidity is about venty-five per cent. The wind velocity is very conlerable, averaging about eleven miles per hour, the evailing direction being from the north and northwest. The most notable features, then, of the climate of this gion are the great extremes of temperature, the great ily and monthly ranges, and the excessive cold of winr. From the fact, however, that spring rapidly adnces during the latter part of April, and that the day mperatures in summer are high, with a good deal of nshine, the wheat matures quickly. There is no malia, and, as has been said, the climate is a wholesome e for the robust, and immigration is rapidly filling up is great fertile region. *Edward O. Otis.*

WINTERGREEN.—(*Gaultheria;* Checkerberry; Boxrry; Partridge-berry; Tea-berry, etc.)

The dried leaves of *Gaultheria procumbens* L. (fam. *icaceæ*). This plant is a little evergreen undershrub, ith slender, weak, creeping or subterranean stems, and at intervals ascending or erect; branches from two to four inches high, each bearing three or four leaves and a few axillary, nodding flowers; leaves oval or obovate, thick, leathery, almost entire, bright-green and shining above, paler beneath, with slightly revolute margins, fragrant when crushed, and pleasantly aromatic to the taste. Flowers small, calyx five-toothed, enclosing the small capsule, becoming fleshy as it ripens, and forming the principal portion of the pleasant-flavored fruit. Corolla ovoid, five-toothed; stamens, ten; pistil, one, with five-celled ovary; pod, five-celled, many-seeded, surrounded by the juicy calyx. The berry, which is edible and occasionally found in the markets, is about a fourth of an inch in diameter, pink or red in color, of a sweetish, aromatic, birch-like taste.

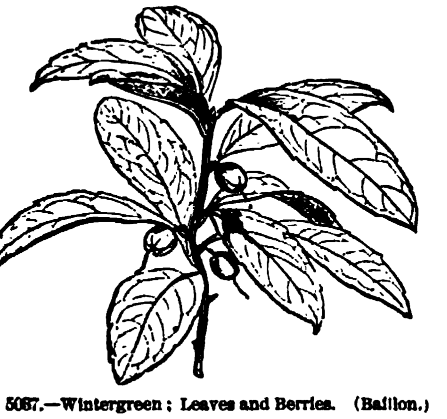

FIG. 5067.—Wintergreen; Leaves and Berries. (Baillon.)

Gaultheria is a native of North America, growing in dry woods and plains. It is in many parts of the United States very abundant, carpeting the ground under trees and bushes, and is collected in large quantities both for use, dried, and for immediate distillation. All parts are aromatic, the leaves and stems astringent as well, and owe their value to an essential oil (*Oleum Gaultheriæ*, U. S. P.) of birch-like flavor, consisting mostly of *methyl salicylate*, with about one-tenth of a peculiar hydrocarbon, *gaultherilene*. Oil of wintergreen is "a colorless, yellow or reddish liquid (according to age), of a peculiar strong and aromatic odor, a sweetish, warm, and aromatic taste, and a slightly acid reaction. Specific gravity about 1.180. It is readily soluble in alcohol."

Like sassafras, cinnamon, and other pleasant aromatics, wintergreen is very largely used as a flavor, and enters into several official preparations for that purpose. Its relation to salicylic acid has led to its employment in rheumatism. The discussion is very animated as to whether oil of wintergreen, oil of birch, and pure methyl salicylate are identical in physiological action. By many the natural oil of wintergreen is preferred to either of the others. Dose of the leaves, 1–4 gm. (gr. xv.–lx.); of the oil, from five to twenty drops.

Preparations: Of the oil, spirit (*Spiritus Gaultheriæ*, U. S. P.) 0.05 in alcohol. *W. P. Bolles.*

WITCHHAZEL.—(*Hamamelis*, U. S. P.) The dried leaves of *Hamamelis Virginiana* L. (fam. *Hamamelidaceæ*) The plant yielding this drug is a tall, slender, straggling shrub growing commonly, in moist woods, over a large part of the United States. Its flowers are small, in little, sessile, axillary clusters, and appear late in the autumn. They persist through most of the winter, the fruit from them ripening in the following summer. Calyx four-parted; corolla of four long, narrow, strap-shaped, yellow petals; stamens, eight, short; pistil, one, with two styles; and a two-celled, two-ovuled ovary.

The leaves should be collected in the autumn. They are stoutly and very shortly petioled, the blade 7–15 cm. (3–6 in.) long and nearly as broad or occasionally even broader, highly inequilateral, oval, with a very oblique, slightly cordate base and usually a very short obtusish point at the summit, the margin coarsely sinuate; thickish, dull green and with obscure venation above, paler or brownish-green, with a satiny lustre and very prominent principal veins underneath, nearly smooth, the few hairs of the lower surface having much thickened walls and a very small lumen; odor rather faint, characteristic; taste astringent, slightly aromatic, bitter.

A number of analyses of this plant have been made without discovering anything to explain its reputed virtues. It is not poisonous in any quantity. There is some *tannin*, and an infinitesimal amount of *essential oil;* enough to give smell and taste to a distillate, but scarcely enough to isolate.

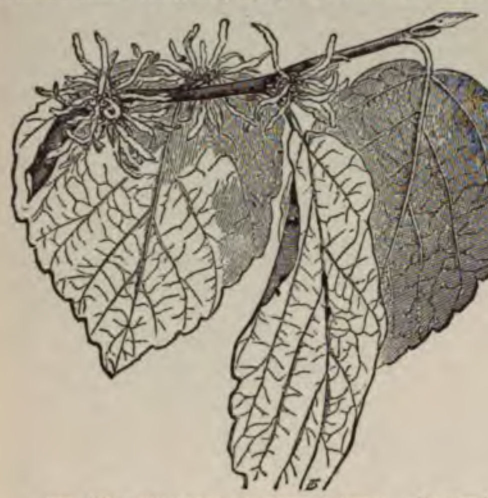

FIG. 5038.—Witchhazel; Flowering Branch. (Baillon.)

It is an old remedy of the Indians, and is said to have been introduced to our notice by them; but its present popularity as a wash for bruises and wounds in household practice is of very modern growth.

For twenty years or so it has been, in this country, the most widely used domestic vulnerary, taking the place in the popular estimation of arnica, which had held sway for a generation before. It is usually employed in the form of a distillate, made by distilling a very weak mixture of alcohol and water (six-per-cent. alcohol). It has an odor and faint taste derived from the drug, but not enough oil or extract to be estimated in any other way. The odor is pleasant and suggestive of liniment, and the preparation is on the whole a fair evaporating lotion. A fluid extract (*Extractum Hamamelidis Fluidum*) is official, and contains, besides the fragrant principles, considerable tannin, which the distilled preparation of course does not. It may be diluted for washes, vaginal douches, etc. Witchhazel at present is rarely given internally.

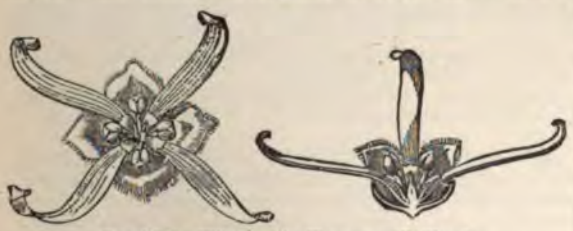

FIG. 5039.—Witchhazel; Flowers. (Baillon.)

The bark is similarly employed, and much of the distillate is said to be prepared from it. It is regarded by many as being superior to the leaves.

Henry H. Rusby.

WITTER'S MINERAL SPRING.—Lake County, California.

These springs are pleasantly located about one mile east of Pearson's Springs, five miles from Upper Lake, and three miles from Blue Lake. The altitude is 1,800 feet. The resort is a growing one, and is very picturesquely located, having excellent views of the lakes, valleys, and mountains in the vicinity. There are a good hotel, several cottages, and fine bathing facilities for hot and cold mineral baths. The springs are all cold and flow about sixty gallons an hour. There are cold soda and iron springs, and cold sulphur springs. The principal spring is composed as follows: One United States gallon contains (solids): Sodium chloride, gr. 17.42; sodium carbonate, gr. 5.96; sodium sulphate, gr. 11.50; potassium carbonate, gr. 3.15; magnesium carbonate, gr. 7.10; magnesium sulphate, gr. 20.62; ferrous carbonate, gr. 1.17; manganese carbonate, gr. 0.86; alumina, gr. 1.65; borates, gr. 0.42; silica, gr. 6.33; organic matter, gr. 0.76; total solids, 76.94 grains. Carbonic acid gas, 7.65 cub. in.; sulphureted hydrogen, 5.25 cub. in. Temperature of water, 59.3° F.

This spring has received the very emphatic if not euphonious title of Dead Shot Spring, having reference to the action of the water on the diseases for which it is recommended. The water is said to be highly efficacious in liver, kidney, and bowel disorders.

James K. Crook.

WOLFER'S MINERAL SPRING.—Marion County, Oregon.

POST-OFFICE.—Hubbard. Hotels.

ACCESS.—Viâ Southern Pacific Railroad to Hubbard, thirty-one miles from Portland and twenty miles from Salem. The spring is within five minutes' walk of the depot.

This spring is mentioned as "Lehman's Spring" in the Geological Reports for 1895. Hubbard is situated in the Willamette valley, in the midst of a fine fruit and garden country. The spring (artesian) is located on the hillside, at a level of 212 feet above the sea. It is surrounded by an arbor of wild willows, and forces its way to a height of four feet above the surface, forming a beautiful fountain. It yields about six thousand gallons of water per hour. There are beautiful grounds about the springs, well adapted for outdoor sports, picnics, etc. According to a partial analysis by Professor Fisk, the water contains: Calcium carbonate, magnesium carbonate, sodium chloride, potassium chloride, iron oxide, silica, and alumina. The water is said to possess valuable properties as a tonic and laxative. *James K. Crook.*

WOOD-TICK. See *Arachnida.*

WOOL-SORTERS' DISEASE. See *Anthrax*, and *Occupation, Hygiene of.*

WOOTAN WELLS.—Robertson County, Texas.

POST-OFFICE.—Wootan Wells. Hotel and cottages.

ACCESS.—Viâ Houston and Texas Central Railroad to Wootan Junction; thence two miles to springs. Street cars meet all trains, day and night, from about April 1st to November 1st; during the winter months there are only day trains.

The location is 145 miles north of Houston, and 125 miles south of Dallas. These wells are located on a picturesque eminence about 500 feet above the level of the gulf. The first well was dug in 1877 by Mr. F. M. Wootan, an emigrant from Alabama. The water was found to be useful for cooking or washing purposes, so Mr. Wootan rented the farm on which the well was situated to a neighbor, whose health was bad and who also had a puny wife and children. They found it necessary to use the "bad" water for drinking purposes, and the sickly family all got well and remained well. This was the beginning of a health resort which has now become widely and favorably known. Persons with means became interested. More wells were dug, and at this time about all the attractions of any first-class interior watering place will be found here. These include a large, well-arranged brick hotel, with abundant bathing facilities, an opera house, archery court, croquet grounds, beautiful groves, camp grounds, etc. The place is naturally well adapted for good drainage, and no pains are spared by the management to keep the surroundings in a sanitary condition. The resort is open the year round. Analyses of the different wells show very little difference in their chemical ingredients. Following are specimen analyses of two of the wells, the first by Prof. Charles F. Chandler, of New York, and the second by Dr. W. M. Mew, chemist of the United States Naval Department, Washington, D. C.:

Well No. 1.—One United States gallon contains (solids): Chlorides, gr. 23.34; magnesium, gr. 13.11; calcium, gr. 25.21; iron protoxide, gr. 1.20; iron sesquioxide, gr. 0.69; aluminum sesquioxide, gr. 1.22; manganese oxide, gr. 0.54; sulphates, gr. 59.67; silica, gr. 3.28; organic and volatile matter, gr. 9.62. Total solids, 137.88 grains.

Well No. 4.—One United States gallon contains (solids): Chlorides, gr. 36.36; magnesium, gr. 22.75; calcium, gr. 28.18; iron sesquioxide, gr. 13.06; aluminum sesquioxide, gr. 3.45; manganese oxide, gr. 0.57; sulphates, gr. 86.41; sodium, gr. 18.10; silica, gr. 4.69. Total solids, 213.57 grains.

These waters show about the same general characteristics, No. 4 being somewhat richer in mineral ingredients, especially in iron, than No. 1. It will be observed that the chemists have not worked out in full the combinations of the various elements present. There can be no doubt, however, that the most important compounds contained in the waters are the sulphates of magnesia and soda, and probably the sulphate of iron. These ingredients should impart, in the proportions here probably present, mild cathartic properties, and, in No. 4 especially, the effects of a strong ferruginous tonic and blood restorer. The waters are highly prized by Texas physicians in the treatment of the various forms of nephritis and in diabetes and rheumatism. They are of undoubted efficacy in some cases of dyspepsia and in catarrhal jaundice and other disorders of the liver and alimentary tract. The water is used commercially, and is shipped to various parts of the United States. *James K. Crook.*

WORMSEED, AMERICAN.—(*Chenopodium*, U. S. P.; *Ansérine vermifuge*, Codex Med.) The dried ripe fruit of *Chenopodium ambrosioides* L. or of *C. anthelminticum* L. (fam. *Chenopodiaceæ*).

The first-named species is the old-fashioned garden plant *Mexican tea* or *Ambrosia*, native of tropical America; the second appears to be of European nativity. Both are common weeds in the Eastern United States, growing along roadsides, about wharves, lumber yards, etc., and are of a sprawling and ascending habit, reaching a height of two or three feet. They have a strong, heavy odor, disagreeable to most people. The fruits, generally called "seeds," are nearly $\frac{1}{12}$ of an inch (2 mm.) in diameter, depressed, globular, glandular, dull-greenish or brownish, the integuments friable, containing a lenticular, obtusely edged, glossy, black seed. This seed has a peculiar, somewhat terebinthinate odor, and a bitterish, pungent taste.

The fruits contain one or two per cent. of a rather disagreeable, minty, essential oil, which represents it medicinally. This oil is usually distilled from the entire herb. It is a thin, and, when fresh, colorless liquid of aromatic odor and bitterish taste; specific gravity, 0.920.

Like most aromatic herbs, chenopodium, in small doses, is a stomachic tonic; in large doses it is irritating and nauseating. The property for which it is mostly prized is, however, its poisonous action upon intestinal worms, particularly upon the lumbrici. From five to fifteen drops of the oil in emulsion or on sugar is the usual range of doses. Oil of Chenopodium is a very powerful poison in overdoses. The symptoms are chiefly referable to intestinal irritation and cerebral congestion. There are drowsiness, great thirst, abdominal pain, perhaps with vomiting, intense sensitiveness to light and sound, but with indistinctness, aphasia of both kinds, stupor, coma, and death. The treatment is stomach evacuation, purging, with watery stools, free administration of water, enemata, brandy, and external heat.

W. P. Bolles.

WORMSEED, LEVANT.—(*Santonica*, U. S. P.; *Flores Cinæ*, P. G.; *Flores Artemisiæ, Semen Contra, S. Sanctum.*) The dried unexpanded flower-heads of *Artemisia pauciflora* (Ledeb.) Weber (fam. *Compositæ*). Although the plant yielding these flower-heads is well known, there is great difference of opinion among botanists as to its specific reference. By many it is regarded as a variety of *A. maritima* L. of Southern Europe. The German Pharmacopœia still refers the drug to *A. Cina* Berg. The drug is collected in the Turkestan deserts, and most of it, and the best, is at once consumed there in the manufacture of santonin, the percentage of santonica exported being steadily on the decrease. Several related and similar, but hairy products have occasionally been imported from India and Africa, and chenopodium is occasionally sold for it. The drug is also subject, through imperfect cleaning, to the presence of pieces of branchlets and leaves, and dirt of various kinds; yet it is usually clean and of fine quality. It deteriorates readily on being kept, especially if not carefully protected in a closed and dark container. In proportion as the greenish-gray tinge has changed to a brown, it may be regarded as having thus deteriorated. The drug is thus described:

A yellowish-green (at length greenish-brown) somewhat glossy, mobile mass: having a strong and peculiar, somewhat camphoraceous odor and an aromatic and bitter taste; heads 2–4 mm. ($\frac{1}{12}$–$\frac{1}{6}$ in.) long, oblong-ovoid, slightly flattened, obtuse, consisting of an involucre of about twelve to eighteen closely imbricated, glandular scales with broad midribs, enclosing four or five rudimentary florets.

With gum, a little resin, and ordinary plant constituents, three specific bodies exist in santonica. Its one and one-half to two per cent. of volatile oil consists chiefly of cineol, and is somewhat like oil of eucalyptus in properties. Santonin, of which there is usually not more than two per cent., as the drug occurs here, is the active anthelmintic agent and is described under that title. A small and variable amount of artemisin occurs, obviously resulting from the oxidation of santonin.

Although santonica possesses, in correspondingly lower degree, the anthelmintic properties of santonin, the latter alone is used for that purpose. As an aromatic bitter, santonica is occasionally used in doses of 0.3–2 gm. (gr. v.–xxx.). There is no official preparation.

Henry H. Rusby.

WORMSEED, POISONING BY. — *Chenopodium ambrosioides* L.; and *C. anthelminticum* Gray, which are possibly only varieties of one species, contain a volatile oil which has a strong, disagreeable odor, and decided vermifuge properties. It is most abundant in the seeds. It is somewhat analogous in composition to oil of turpentine. By keeping it undergoes oxidation, and probably other changes. The seeds of the plant are used as a remedy for intestinal round worms and are often given to children as a domestic remedy. Little harm appears to result from this practice, but the use of the oil itself has led to fatal results in several cases. One of the earliest of the American cases to be fully reported was that by Dr. Brown in the *Maryland Medical Journal* in 1878. A man, aged thirty-one years, was supposed to have taken over an ounce of the oil, purposely substituted by him for castor oil. He suffered from nausea, later with severe vomiting, dizziness, buzzing in the ears, diminished sensitiveness to some sounds and hypersensitiveness to other sounds. Still later, marked aphasia and confusion of ideas occurred. He died five days after the material was thought to have been taken. He was, however, a confirmed self-drugger, and deceived the attending physician throughout the whole history of his illness, denying that he had taken the oil, though the odor of it was unmistakable. Another case was that of a child, aged two years, to whom was given one teaspoonful of the oil. The immediate symptoms were deep sleep, clammy skin, and muscular weakness. Brandy and milk were given. The patient became restless and was quieted with bromides. She became somewhat better, but then became worse, could not stand up or walk alone, and vomited material which had the odor of the oil. Her hearing was for a while affected. She recovered.

In another case a boy, aged three years, was given a teaspoonful of the oil. He vomited and then went into a stupor. The pupils were small but equal; pulse, respiration, and temperature normal. Salt water was given as an emetic, then one grain of calomel, and repeated doses of castor oil. He became worse, developing deep stupor and twitching of the arms, and died. In another case a man, aged sixty-three years, died after taking, in divided doses during the course of a single day, one ounce of the oil. No direct antidotal treatment was employed. He was comatose.

The disturbance of hearing noticed in several of the cases is a remarkable feature, but has not been explained. It must be borne in mind that in some of the cases the amount taken and the exact nature of the material were not established. From the reports it appears that the oil is actively toxic, and that caution should be given in works on materia medica concerning its use. Very little is said upon this question in the standard works. Its effects seem to be both as an intestinal irritant and as a neurotic poison. The odor will probably afford the best means of making a diagnosis. No characteristic post-mortem changes are recorded.

Treatment will be difficult. Early and free evacuation of the stomach and bowels is important. Strong coffee might be useful. Irritating emetics are contraindicated.

Henry Leffmann.

WORMWOOD.—(*Absinthium*, Vermouth.) "The leaves and tops of *Artemisia Absinthium* L. (family *Compositæ*)," U. S. P. A half-shrubby plant, with numerous erect stems two to four feet high, grayish silky throughout. The leaves are nearly equally gray on both sides, twice or thrice pinnatifid, the divisions oblong and obtuse, the larger ones three or four times as long as broad. The small heads are short-peduncled, solitary, and cernuous in the axils of leafy bracts, and the floriferous branches are panicled. The characters of flowers and fruit will be found described under *Artemisia*. The odor is strongly aromatic and the flavor very bitter.

The plant is native to Asia and perhaps Europe, and has become extensively naturalized in nearly all temperate countries, and even in the tropics, at high altitudes.

The activity of absinthium depends upon the two constituents: *absinthol*, which constitutes the most of its one per cent. of volatile oil, and *absinthin*, a bitter glucoside, soluble in both alcohol and water. In its volatile oil occurs also the blue oil of chamomile flowers. Oil of wormwood is an important commercial article, being largely in demand in France for the manufacture of the alcoholic beverage *absinthe*. Tannin, resin, and succinic acid also occur in this drug. Absinthium is an aromatic bitter, acting like chamomile, especially as a gastric tonic. It is also mildly antiperiodic and anthelmintic. The oil has specific nervine properties, a dose of half an ounce having caused alarming symptoms, with convulsions and insensibility. An absinthe habit is formed by the continued use of the liquor, the victims suffering from neuralgia, muscular tremors, epilepsy, and impaired intellect. Observations have established the fact that these effects are due to the absinthium and not to the alcohol. The dose of the herb is 1-4 gm. (ʒ ¼–i.); of the oil, ♏ i.–iij. Large quantities of the oil would undoubtedly prove fatally poisonous.

Henry H. Rusby.

WRIST, JOINTS OF THE.—The skeleton of the wrist, being a series of small bones essentially similar in character, may be considered as a whole, and we may hence conceive a superior radiocarpal or wrist-joint proper, between the bones of the forearm and the carpus, and an inferior or carpometacarpal joint, between the carpus and the metacarpus. Again, we may consider separately the two rows of carpal bones, and regard the somewhat irregular union between them as an intracarpal or mediocarpal joint. Finally, we may consider each bone as a separate unit and its union with each of those which it touches as so many carpal joints of a secondary degree.

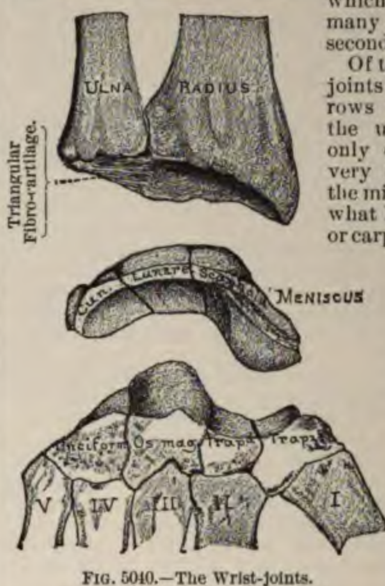

FIG. 5040.—The Wrist-joints.

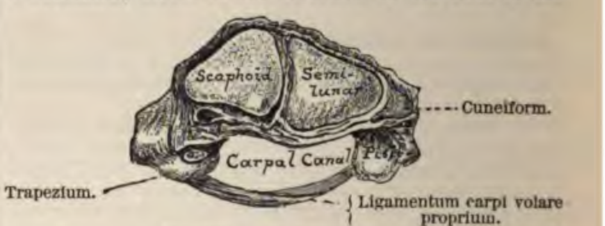

FIG. 5041.—The Carpal Canal.

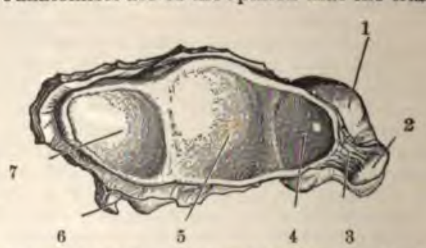

FIG. 5042.—Articular Surface of the Wrist-Joint. (Cunningham.) 1, Head of ulna; 2, styloid process of ulna; 3, apex of triangular fibro-cartilage; 4, triangular fibro-cartilage; 5, surface of semilunar bone; 6, groove for tendon of extensor longus pollicis muscle; 7, surface for scaphoid bone.

Of the three transverse joints formed by the rows of carpal bones, the upper one is the only one that has any very marked mobility, the middle one has somewhat less, and the lower or carpometacarpal joint has the least of all. It is, indeed, instructive and logical in regarding the movements to follow the plan adopted by Meyer, and consider the lower row of bones as combined for practical purposes with the metacarpal bones with which they articulate and the upper row as an articular integer or meniscus which is the essential interposed element between the forearm and the hand. Viewing the form of the surfaces, the articulation between the meniscus and the forearm is a pommel or ellipsoidal joint. Movement is necessarily freest in the direction of the axes of the ellipsoid, but still a certain amount of rotation is possible. The surfaces involved are those of the triangular cartilage and the radius above, and the scaphoid, semilunar, and cuneiform below. The ulna does not enter into the articulation, nor does the pisiform bone. Many comparative anatomists are of the opinion that the triangular fibro-cartilage represents a carpal element which in its complete form long ago vanished from the mammalian carpus and that the pisiform bone is another vestige of the same kind. Certain facts of abnormal variation seem to support this view and to show that the pentadactylate form of the human hand is not the primitive form, firmly fixed though it now is, but that a seven-digit hand was probably the original mammalian type. Odd cases of supernumerary wrist-bones and fingers, which are occasionally seen, are, according to this view, instances of atavism.

The midcarpal joint is of a mixed character, having, like the midtarsal joint of the foot, a wavy outline, the comparatively large, convex upper surfaces of the os magnum and unciform bones making together a sort of ball-like head which fits into the hollow socket made by the under surfaces of the combined scaphoid, semilunar, and cuneiform bones; while a comparatively small surface of the scaphoid articulates with the trapezium and trapezoid to make a curve in the opposite direction. This assists considerably in twisting movements of the hand, such as pronation and supination, which are very necessary to that nicety in the management of tools which characterizes the hand of man. The hand of the ape is by no means so delicately adjusted in this particular.

It has been well pointed out by Professor Humphrey, in his classical treatise on the "Human Skeleton," that the wrist owes the security of its joints, not so much to the interlocking shape of the joint surfaces, or to the strength of its ligaments, as to the strong tendons which pass over it, tend to protect it, and render it at the same time flexible. A short examination of the lower end of the radius will show that its dorsal aspect is deeply grooved for the extensor tendons which pass in every direction over the back of the hand. They are bound closely down in their grooves by a strong band of fascia called the posterior annular ligament, which thus becomes, as it were, one of the most powerful protecting ligaments of the radiocarpal joint. In a similar manner the anterior surface of the wrist is hollowed out by a deep archway, the carpal canal, so called because it is spread over by strong bands of fascia which confine the flexor tendons in a sort of subway.

English anatomists group these bands together indiscriminately as the anterior annular ligament, but there can readily be distinguished two bands—a superficial one, to which the name of annular ligament may properly be applied, as it is a process of the deep fascia of the arm which passes over the tendon of the palmaris longus and the ulnar vessels and nerve, being continuous with the posterior annular ligament at either side; the second is more independent, partaking more of the nature of a ligament, and therefore properly designated as the ligamentum carpi volare proprium. It is a strong, firm band, attached on either side to the carpal eminences—that is to say, the pisiform and unciform bones on the inner side and the tubercle of the scaphoid and the ridge of the trapezium on the outer side. It passes *under* the tendon of the palmaris longus and the ulnar vessels and nerve. Beneath it pass the great flexor tendons and the median nerve, confined by several strong sheaths which blend with each other and send fascial processes to the ligament above and the attachments of the special bones below. It is to this arrangement, combined with pronation, that we owe the surprising flexibility which characterizes the wrist, a flexibility which permits the extraordinary twists so famous in the pitching of a ball, the handling of a tennis racket, and the parrying of the thrust of a foil.

FIG. 5043.—Ligaments on Anterior Aspect of Radiocarpal, Carpal, and Carpometacarpal Joints. (Cunningham.)

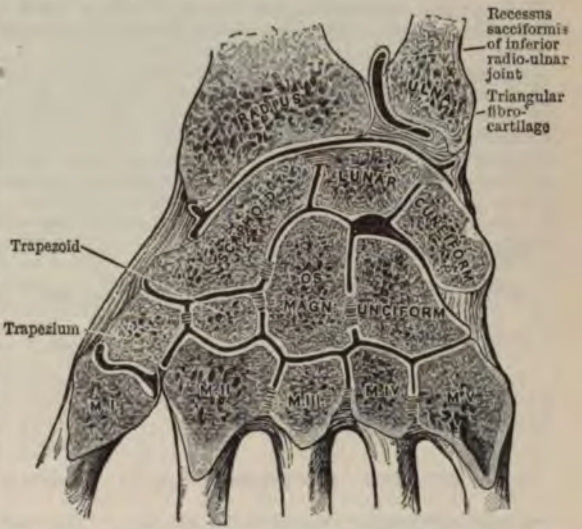

FIG. 5044.—Coronal Section through the Radiocarpal, Carpal, Carpometacarpal, and Intermetacarpal Joints, to show Joint Cavities and Interosseous Ligaments (diagrammatic). (Cunningham.)

Viewing the wrist-joint with reference to its synovial cavities, we find that the radiocarpal joint has its own cavity, the midcarpal and carpometacarpal having a common cavity, there being excluded two bones, the pisiform and the metacarpal bone of the thumb, each of which has its own special articulation—the first with the cuneiform, the second with the trapezium.

The intrinsic ligaments of the carpus are of two classes: one being external strengthening bands, the others internal, interosseous, serving as close interties to keep the whole system firm. On the palmar surface a somewhat irregular mass of fibres, stretching from the bones of the forearm to the metacarpal bones, has received the name of the ligamentum carpi volare profundum.

Separate portions of this have received different names. Thus the arcuate ligament is that portion which passes downward and inward from the radius to the cuneiform bone; the straight ligament (ligamentum carpi rectum) is a rounded fasciculus that passes from the styloid process of the ulna to the semilunar and cuneiform bones, and the funiculus ligamentosus a similar one extending from the same to the cuneiform and pisiform bones. Bands from the pisiform bone to the unciform and to the fifth metacarpal (ligamentum piso-hamatum, ligamentum piso-metacarpeum) are regarded as extensions of the insertion of the flexor carpi ulnaris. A series of short bands connecting the os magnum with the contiguous bones is known as the radiate ligament. Finally, the most distal band, connecting the bases of the metacarpal bones, is known as the deep transverse ligament. All these divisions seem hardly necessary.

The investment on the dorsal surface is not usually so complete. The strengthening bands are mainly two—the rhomboid ligament, passing downward and inward from the lower end of the radius to the cuneiform and unciform bones, and the transverse dorsal ligament, extending from the scaphoid outward to the same. There is also a dorsal radiate ligament diverging from the os magnum.

The only other joint requiring especial mention is that of the metacarpal bone of the thumb with the trapezium. This is an excellent example of the joint by reciprocal reception, sometimes termed the saddle-joint. Its motions are freest in two directions, which correspond to the motions of adduction and abduction on the one hand, and of the various adjustments of opposition on the other.

XANTHELASMA, XANTHOMA. See *Eye, Tumors of.*

XANTHORRHŒA RESIN.—*Resina lutea; Acaroides Gum* or *Resin; Botany Bay Gum* or *Resin.* By these names are designated several closely related solid balsams, obtained in Australia from species of *Xanthorrhœa* (fam. *Liliaceæ*).

The resinous sap exudes spontaneously, and hardens upon the stem in tears or masses. Two principal varieties of the "gum" are distinguished: the red, in deep red lumps or fragments resembling lumpy specimens of dragon's blood, having a weak odor of benzoin, and a spicy cinnamon-like taste; the yellow, in orange-yellow pieces or tears, having a strong benzoin odor.

The balsam contains, besides some bassorin and uninteresting ingredients, a large proportion of *cinnamic acid* and some *benzoic acid.* When it is decomposed with melted potash, parabenzoic and protocatechuic acids, pyrocatechin and resorcin are formed. In nitric acid the balsam dissolves readily, and yields abundance of picric acid, together with oxalic and nitrobenzoic acids.

The *xanthorrhœa* resins have long been used in Australia as a remedy for gastric troubles, intestinal catarrhs, diarrhœas, etc., and are occasionally prescribed in this country for similar conditions; but their principal uses are in the arts as a source of picric acid, and in the manufacture of lacs and varnishes.

Dose, from 0.5 to 1 gm. (gr. viij. ad xvi.). It may be given in alcoholic solution.

XYLOL.—A hydrocarbon, or mixture of isomeric hydrocarbons of the composition $C_6H_4(CH_3)_2$, occurs as a constituent of coal-tar, and is known as *xylol* or *xylene.* This substance is principally *metaxylene* (*metadimethylbenzene*), with a certain proportion of *paraxylene* (*paradimethylbenzene*), and possibly some other hydrocarbons. Pure metaxylene can be obtained by special processes. Xylol is a thin, colorless fluid of a faint odor, reminding somewhat of that of benzene, and of a burning taste. It is insoluble in water, but soluble in alcohol. Medicinally, xylol has been used in the treatment of smallpox, and had at one time an ephemeral, but undeserved, reputation as a remedy for the disease. It was administered internally in doses of from ten to fifteen drops, in emulsion, and was also applied locally to the throat. It is now obsolete as a medicine.

Edward Curtis.

YADKIN MINERAL SPRINGS.—Stanley County, North Carolina.

Post-Office.—Palmersville. Boarding-houses.

Access.—Viâ Southern Railroad to New London, thence six miles by private conveyance to springs.

This resort is charmingly located in a wild and picturesque region penetrated by the Yadkin River, and covered by the Oconsechee Range of mountains. Like the usual North Carolina mountain climate, the atmospheric conditions prevailing in this section are eminently conducive to good health and longevity. The rainfall at the springs is about fifty-three inches annually, and is quite uniformly distributed through the seasons. There is no hotel, but during the season, from May to November, accommodations may be obtained at a reasonable rate in a number of private boarding-houses. The springs are two in number, a chalybeate spring yielding sixty gallons of water per hour, and a sulphur spring flowing at the rate of one hundred and eighty gallons per hour. No qualitative analysis is available. Much beautiful scenery is found in the neighborhood of the springs; the falls of the Yadkin River, the Narrows, and the "Devil's Den," a great cave in the hills, being the most prominent.

James K. Crook.

YARROW.—*Achillea, Milfoil. Achillea* L. (fam. *Compositæ*) is a genus of more than one hundred species, several of which, from ancient times, have been used in domestic and professional medicine. The most important of these is *A millefolium* L., the herb of which is used. It is a perennial plant, indigenous to Asia and Europe and largely naturalized (or perhaps native) in North America. Its active principles are a very small amount of a volatile oil, and the bitter glucoside *achillein.* Aconitic acid also occurs, with considerable tannin, a little gum and resin. The drug is to be classed as an ordinary aromatic bitter, somewhat like chamomile. The dose varies from 0.3 to 2 gm. (gr. v. to xxx.).

Henry H. Rusby.

YAWNING.—(Synonyms: Gaping, Oscitation; Germ., *Gähnen;* Fr., *Bâillement.*)

Definition.—Yawning is a physiological modification of respiration by which the act is intensified. It consists in an involuntary, forcible, and profound inspiration, followed by a pause and a prolonged expiration. When fully developed, it is accompanied by a wide opening of the mouth, an elevation of the velum palati, and depression of the larynx, a roaring sound, and usually a click in each ear, a flow of saliva, and a suffusion of the eyes with tears, and a more or less imperative impulse to extend the limbs, especially the arms (pandiculation), to bow and twist the trunk, and to throw back the head. The inspiratory act is frequently audible, and the expiration usually acquires a distinct blowing sound. The elevation of the palate closes the posterior nares and causes the air to be admitted wholly through the mouth. In the same way the Eustachian tubes are closed, causing momentary obtunding of hearing. The contraction of the palatal muscles often precedes the opening of the mouth, and tends to persist for a moment after its closure. The commencement of their contraction is not infrequently accompanied by a rapid succession of three or four short, broken inspiratory efforts

Physiology.—Yawning is a physiological expression of fatigue and a disposition to sleep. It may, however, arise from a retardation of the respiration, or from any influence which will impair the oxygenation of the blood. It is frequently, therefore, a product of melancholy, languor, ennui, torpor, or debility, or of the malaise which precedes the onset of disease. It is liable to follow prolonged abstraction of mind or concentration of thought. It is sometimes the result of feeble or laborious digestion, of gastralgia, or of other disorder of the digestive organs; or it may occur in response to a demand for increased activity of circulation. It may be sympathetic. To some individuals it is habitual, occurring without fatigue, and being but the outgrowth of the lassitude or indolence of their natures. It may sometimes be attributed to the possession of an inferior degree of intelligence, a slothful, inactive, effeminate, timid, or lustful disposition incapable alike of vigorous mental exertion or of prolonged physical activity.

That yawning may be the response to a demand for increased activity of oxygenation in the lungs is demonstrated by placing an animal in an irrespirable atmosphere. Repeated yawning occurs shortly before the animal succumbs to asphyxia. The phenomenon is therefore usually explained on the supposition that it is due to a stimulus transmitted from the central nervous system in response to a peripheral impression, in most cases arising, in part at least, from the respiratory apparatus. Longet has attributed it to the accumulation of too great a quantity of venous blood in the right side of the heart, whence the peripheral impression is supposed to proceed. From whatever source we derive the peripheral impression, however, the act is generally admitted to be reflex in character. Of the reflex nature of the stimulus which produces the muscle contractions in the extremities, there can be no doubt; for it is a matter of repeated observation that the hand which, owing to paralysis, has been for years beyond control of the will, and has become firmly contracted by post-paralytic rigidity of its flexor muscles, will often become distended during yawning. It is evident here that the stimulus can emanate only from the spinal centres.

The mechanism of yawning is the same as that of normal respiration; the same muscles are called into action, but their movements are more extended. (See *Respiration*, Vol. VI.) The diaphragm, the scaleni, the sternocleido-mastoids, the clavicular portions of the trapezii, the lesser pectorals, the subclaviculars, the external intercostals, the serrati magni, the rhomboids—in fact, all the muscles which normally act as direct or as auxiliary forces in the full expansion of the chest, take part in the inspiratory movement; and all the muscles of forced expiration are called into action in the expiratory stage. In the fully developed yawn there is the action also of the muscles of the face, the depressors of the lower jaw, the dilators of the nostrils and upper lip, the orbiculares palpebrarum, the zygomatics, and of the depressors of the hyoid bone and larynx, and finally of the muscles of the back in the bowing of the trunk, and of the extensors of the extremities when stretching occurs.

Yawning is involuntary. It begins without the sanction of the will, and, once begun, it cannot be arrested. In this it resembles sighing, sneezing, hiccough, and other modifications of respiration, without, however, possessing their full spasmodic quality. Yet the will is not entirely deprived of influence over it; for a yawn may be often in a measure concealed by a forcible effort at closure of the jaws, and the mouth may be closed before the yawn has subsided. It may be imitated, but no amount of effort will induce it unless a sufficient cause for it exist. As Carpenter says, "this act may be performed by the will, though not completely; and is one that is particularly excited by an involuntary tendency to imitation, as every one must have experienced who has ever been in company with a set of yawners."

After yawning there is usually a momentary pause in the respiratory movements, followed by normal, tranquil breathing. The forced respiration has not only supplied the blood with its needed oxygen, but, aided by the muscular contractions, has removed venous engorgement and accelerated the systemic circulation. At the same time, a moment's relaxation has been given to the fatigued body, and a sense of relief is usually afforded.

SYMPTOMATOLOGY.—The value of yawning as a symptom has been at different times very differently estimated. Hippocrates recognized it as a precursor of a fever, particularly of intermittent fever. From its frequency and intensity he prognosticated the severity and duration of the disease. Yawning, with suffusion of the eyes and pandiculation, was in early times among the most valued factors in the diagnosis of the eruptive fevers. Occurring during parturition, it was an evil omen. Roederer, in 1759, believed that he had observed a death from it. The yawning of the infant was also a cause for solicitude.

It is now comparatively seldom, however, that we think of yawning as more than an indication of fatigue and a precursor of sleep, or of lassitude and a lazy disposition. But that it may denote a diseased state of the system is a well-recognized fact. As indicative of fatigue, it may be a symptom of profound mental or physical exhaustion. It may, in fact, of itself constitute a morbid condition of spasmodic nature and of grave import. It is not infrequently indicative of a deficient oxygenation of the blood, especially when it is associated with the dyspnœa which results from the lung consolidation of fibrinous pneumonia, the lung compression of hydrothorax or pneumothorax, or after profuse and exhausting hemorrhages. In the latter connection, it is at times a valuable factor in the diagnosis of concealed hemorrhage.

Modern experience has but confirmed the observations of the ancients with regard to the occurrence of yawning in the prodromal stage of fevers, particularly of the intermittents. In these, as also in such neurotic affections as epilepsy, hysteria, catalepsy, and somnambulism, frequent gaping often signifies the immediate supervention of a seizure. When it occurs during the course of a disease it not seldom indicates the approach of resolution or of a crisis. It is so frequently observed during parturition, however, as a consequence merely of fatigue, that no great significance is now attached to it.

As a symptom of feeble or suppressed menstruation in anæmic young girls, it is probably in most instances a manifestation of hysteria, so often a complication of this disorder. It is probable also that many of the reported cases of spasmodic yawning have been of hysterical origin. Nevertheless, cases have been reported in which yawning of a spasmodic character developed without hysteria, and resembled whooping-cough, spasmodic laughing, crying, sneezing, etc. Of a reflex nature, the affection may be indicative of various disorders of the central nervous system, particularly of cerebral anæmia, of circulatory disturbances in the medulla oblongata, or it may occur in the wake of cerebral hemorrhage. It also shows a predilection for individuals who, from necessity, are confined to small, closely crowded work-rooms, and for convalescents from neuralgic affections, especially cardialgia and hemicrania.

To the surgeon yawning is of interest chiefly on account of its occasionally producing luxation of the lower jaw. The mechanism of this accident is considered under *Dislocations*, in Vol. III. *James M. French.*

YAWS is a chronic, highly contagious disease, probably caused by a micro-organism, confined to certain tropical countries, and characterized by a peculiar cutaneous eruption which goes through the stages of squamæ, papules, and tubercles; it is accompanied by a variable (but generally slight) amount of constitutional disturbance, and tends to recovery.

SYNONYMS.—Yaws is the common name given to this disease in the British colonies and by the negroes from West Africa. Sauvages, in 1759, suggested *frambœsia* as the scientific name, from the resemblance of the split tubercle to a raspberry (*framboise*); though Rat thinks that the characteristic tubercle is more like the top of a pickled cauliflower than a raspberry. Charlouis, in 1881, proposed *polypapilloma tropicum*; and later, Nicholls has suggested *granuloma tropicum* as a more correct and scientific designation. And it is to be regretted that one or other of these two names has not found universal acceptance. Different places, too, have furnished different names for this disease, the chief of which are as follows: In the French West Indies it is called *pian*; in Brazil and the Spanish and Portuguese possessions, *bubas*, *bobas;* in Ceylon, *parangi;* in the Dutch Indies, *patek;* on the Gold Coast, *ajortor, dube, dubea, tongara;* in Calabar, *framosi;* in Congo, *tetia;* in Samoa, *lupani, tomo;* in Fiji, *coko;* in New Caledonia, *tonga, tono;* in the Moluccas, *bouton d'Amboine.*

GEOGRAPHICAL DISTRIBUTION.—Yaws is endemic in the tropics, chiefly in the West India Islands (notably Dominica and Jamaica), Central and South America, Western Africa, Mozambique, Madagascar, Ceylon, Java, the East Indian Archipelago, and Polynesia. Its limits seem to be ten degrees on each side of the Equator; though lately cases have been reported from Kimberley, in South Africa. Negro slaves from Africa probably took the disease to the West Indies. The first account of the affection was given by Oviedo in 1525; he met with it in Hispaniola (now St. Domingo).

ETIOLOGY.—The direct cause of the disease is undoubtedly a micro-organism, but so far it has not been absolutely identified. Hirsch, Pierez, and Nicholls and Watts have reported the finding of a micrococcus, to which they ascribe the disease; Breda attributes yaws to a bacillus; and Powell to a yeast. Yaws is generally acquired by direct contagion, and is inoculable through a sore, or an abrasion of the skin, also by the nipples of a nursing mother or the mouth of an infant; but flies, mosquitoes, and other insects may also be the means of disseminating the disease. It is also transmitted by clothes, rugs and mats, and dirt from the floor or walls of filthy and infected hovels. As predisposing factors may be mentioned: *Age.* Infants below one or two years are generally exempt; children between two and fourteen years are most liable to be attacked by the disease. *Sex* has but little influence, the number of males affected being slightly in excess of the females. *Race.* The negro is much more liable to yaws than the white man or mulatto. *Hygiene* is an important factor in this apparent immunity of the whites; and the negro's absolute ignorance of and indifference to things hygienic will go far to explain his susceptibility to yaws. A constitution worn out by disease or dissipation and unhygienic surroundings are potent predisposing factors. *Heredity* plays no part, for children are not born with yaws; this is an important difference between this disease and syphilis. But Hallen has reported a case of yaws in an infant twenty days old. The mother was suffering from yaws and the child probably got infected during labor. *Vaccination* seems to have a favorable influence on the disease. In persons who have been vaccinated an attack of yaws is generally very mild, while a similar result is often experienced from vaccinating a person suffering from yaws. One attack of yaws usually confers *immunity* from future attacks, at any rate for a number of years; but occasionally a person acquires the disease a second or even a third time.

SYMPTOMS AND COURSE OF THE DISEASE.—The disease begins with a *period of incubation*, of from two to eight weeks (but generally nearer the former figure), and lasting till the appearance of the local lesion. Usually there are no prodromes, and occasionally there are a few vague symptoms, such as malaise, languor, headache, itching, pains in the limbs, vertigo, constipation, fever, and palpitation of the heart. In children these symptoms are apt to be more pronounced. This is followed by *the eruptive stage*, which may last for a period varying from a couple of months to as many years. The symptoms mentioned above become more pronounced, and the skin becomes dry, scaly, and lustreless, and in the negro lighter in color. This squamous eruption soon gives place to papules, one or more of which may sometimes be found, on close examination, at the seat of the inoculation. These papules at the point of inoculation may either heal (with treatment in about two weeks, or without treatment in about two months), or break down and ulcerate. They are most apt to appear on the face, perineum, areola of the breast, genitals, anus, toes, lips, mouth, and nose, also at the junction of the mucous membranes with the skin. The papule, which at first is about the size of a pinhead, grows to the dimensions of a pea or a pingpong ball, or even larger. It is conical in shape, and the skin over it becomes thinner and redder and more shiny, and eventually splits in the centre of the tubercle or granuloma, as it is now called. On the splitting of the skin there appears a raw protuberance which seems to push itself through the epidermis; this is the "*framboise*," and is often covered with an offensive exudate of a dull seropurulent fluid, which forms a scab; and this, if removed, is replaced by new crusts. The surface under these crusts is red except in cachectic individuals, when it is of a dirty-yellow color. These tubercles are either single or they coalesce, or they may appear in successive crops; they are the essential lesion of yaws. They may measure as much as two or three inches in diameter, and a quarter of an inch in thickness. They are not painful or tender to pressure, except when they are situated in the palms of the hands or the soles of the feet or under the nails. When situated in the axilla or on the thigh they are apt, from pressure, to become flat. The tubercles gradually shrink, and the scabs or crusts drop off, leaving only a macule which itself eventually disappears. The lymphatic glands in the immediate neighborhood are sometimes involved, in which case they become swollen, and may even suppurate. During this stage some squamæ and papules may also be present. A few papules occasionally remain after the others have disappeared, and are called by the negroes "*memba*" *yaws* ("*memba*" being equivalent to *remember*). In a mild case of yaws there are no sequelæ; but in severe cases and in the debilitated and dissipated there may be serious ulceration, also bone lesions; but the latter are more apt to be a result of syphilis, and the possibility of this disease being present with yaws must not be overlooked. At the same time care must be taken not to give too much mercury, or serious results may follow, for which the yaws is not responsible.

IRREGULAR VARIETIES.—Occasionally one of the yaws tubercles is larger than the others, is more or less isolated, comes earlier, or lasts longer, and is considered by the negroes to be responsible for the other tubercles; such a one is called a "*maman*" *pian* or "*mother*" *yaw*. When the soles of the feet and palms of the hands are affected, there is apt to be severe inflammation; and the disease thus localized is called *crab yaws, crabs, crappox, tubboes*, or *tubba*. *Ringworm yaws* is the name given when the papules become confluent and are arranged circularly.

Pian d'artre is the name given when most or all of the tubercles are replaced by yellowish spots slightly elevated.

When a number of tiny vesicles remain scattered over the trunk the condition is called *Pian grutelle*. This is an occasional sequel of yaws.

DIAGNOSIS.—The transition of the squamæ to papules and later to tubercles which split and exhibit a tumor with a yellowish discharge, is fairly characteristic of yaws. Syphilis is the disease with which yaws is most likely to be confounded. Hutchinson believes yaws to be a species of syphilis modified perhaps by climate and race, but still syphilis. Pierez, Powell, Nicholls, Rat, and most other observers believe that these two diseases are absolutely distinct. Among the points of difference may be mentioned: 1. Yaws is practically confined to the tropics, while syphilis is found almost everywhere. 2. Yaws is not hereditary; syphilis is hereditary. 3. In yaws the primary lesion when found is a soft ulcer; in syphilis it is a hard chancre. 4. Yaws does not invade the nervous system or viscera; syphilis attacks both. 5. In yaws there is considerable itching; in syphilis none. 6. The eruption in yaws is characteristic and *sui generis*; that of syphilis is polymorphous. These are enough to differentiate between the two diseases; but it must be remembered that both syphilis and yaws can occur in the same patient.

PATHOLOGY.—According to Macleod ("Pathology of the Skin"), the clinical lesions, namely, squames, papules, and tubercles, are stages in the evolution of a common histological process.

I. "*Changes in the Corium.*—1. Blood-vessels: Dilatation, and tortuosity of those in the papillary and subpapillary layers; no thickening of the vessel walls or endothelial proliferation; vessels persist in the granuloma. 2. Cellular infiltrate consists of: (*a*) Plasma cell infiltration at first most marked in the neighborhood of the vessels, follicles, and glands, rapidly becoming diffused; no definite arrangement in rows; no large multinuclear cells or true giant cells. (*b*) Mast cells, connective-tissue cells, and small mononuclear cells; no tendency to organization detected. (*c*) Marked extravasation of polynuclear leucocytes. 3. Fibrous stroma: (*a*) Collagen attenuated where the granuloma is densest; no definite degeneration. (*b*) Elastin similarly affected. 4. Hair follicles, sebaceous glands, and coil glands seemed healthy.

"II. *Changes in the Epidermis.*—1. Marked proliferation and down growth of the interpapillary processes so great in the older lesions as to resemble condyloma acuminatum. 2. Basal layer interrupted. 3. Œdema affecting prickle cells and interepithelial spaces. 4. Disappearance of pigment in the affected area. 5. Transitional layers imperfect. 6. Cornification: marked hyperkeratosis and parakeratosis, with deposition of leucocytes and débris between the horny lamellæ." (Macleod.)

PROGNOSIS.—This is favorable, as the disease nearly always terminates in recovery. Under proper treatment a period of a few months suffices for restoration to health. Very young children and the feeble and dissipated may die of exhaustion.

TREATMENT.—Cleanliness and proper hygiene are the best prophylactic measures. The first step in treatment is the segregation of those afflicted. So necessary has this been found that in some of the West India islands, *e.g.*, Dominica, there are yaws hospitals to which those suffering from the disease must go under penalty of imprisonment. Actual treatment consists in cleansing the patient, then in the use of local antiseptic washes, good nourishing food, and tonics. The drugs most often used are: iron, arsenic, iodide of potassium, mercury. The bowels must be regulated, and any concurrent diseases, such as syphilis, be appropriately treated. In *crab yaws* the feet and hands should be soaked in hot water and the softened skin then pared away till the yaw growth is exposed; it can then be treated as mentioned above.

R. J. E. Scott.

LITERATURE.

Scheube's Diseases of Warm Climates; Hirsch's Geographical and Historical Pathology; a paper by Pierez, in the Transactions of the Pan-American Medical Congress of 1893; an article by Firth in Allbutt's System of Medicine; and an article by Nicholls in the Twentieth Century Practice of Medicine: with the bibliography supplied in each.

YEAST.—(*Cerevisiæ Fermentum ; Leaven.*) The fungus *Saccharomyces Cerevisiæ* Meyer (fam. *Saccharomycetes*), in its commercial forms more or less mixed with vegetable substances constituting its nutrient medium.

The alcohol ferment so well known under the name brewers' yeast, consists chiefly of living cells of the plant named above, mixed according to convenience with starch, sugar, malt, meal, or similar substances, and sometimes with hops.

This little plant consists, in its usual form, of single ovoid cells containing turbid protoplasm and vacuoles (*vide* Fig. 5045, *i*) about the $\frac{1}{2000}$ of an inch in length. These cells, in active yeast, increase in numbers to an incredible extent by budding (Fig. 5045, *ii*, *iii*, *iv*), usually separating almost as fast as the new cells attain any considerable size, but also often, especially upon the surface or where the fermentation is slower, cohering for a while in colonies (*v*); under rare circumstances, mother cells (asci ?) are formed in which two or several cells are differentiated, and finally liberated by the disappearance of the original cell wall; these then grow and bud in the same way as the preceding. During the growth and multiplication of these little cells starch and the different sugars are ultimately disintegrated into alcohol and carbon dioxide. (See the articles on *Bacteria*, *Enzymes*, and *Fermentation*.)

The early history of yeast is lost in antiquity. It is frequently mentioned in the Bible as leaven, and in some shape or another has been, and is, used by nearly all races of mankind; its production in the great beer and spirit breweries of Europe and America amounts to thousands of tons, and it is consumed and often made in nearly every family of Christendom.

As a commercial product, yeast exists in three principal forms: (1) Brewers' yeast (formerly official in England), the skimmings of the fermenting beer vats, containing the plant in a state of high activity, of which the following was the official description: "Viscid, semi-fluid, frothy, exhibiting under the microscope numerous isolated, roundish, or oval cells, or short-branched filaments composed of united cells; odor peculiar, taste bitter"; (2) cake yeast (dry) consists of the above mixed with starch flour or, usually, in this country, Indian meal, rolled and cut into little biscuits and dried; and finally, (3) superseding both the above forms for domestic use in cities and towns, the German or compressed yeast in little moist cakes enclosed in tinfoil, which consists of an almost solid mass of yeast cells with a minimum of starch or sugar. This is made by taking the beer skimmings and repeatedly washing and straining them, and allowing the cells to settle, and finally pressing nearly dry between cloths; or by propagating them in a definite mixture of barley-malt, rye flour, and barley, and collecting, washing, and pressing in the same way. "Compressed" yeast is a very concentrated and active form of yeast. In its moist state, however, it does not keep very well, and should be obtained fresh every day or two, and laid in the ice chest until wanted.

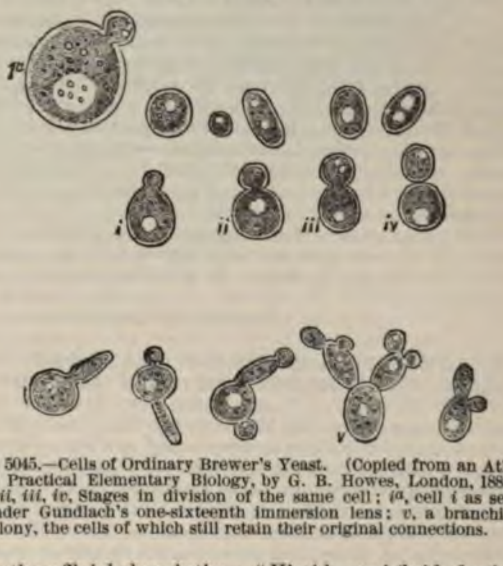

FIG. 5045.—Cells of Ordinary Brewer's Yeast. (Copied from an Atlas of Practical Elementary Biology, by G. B. Howes, London, 1885.) *i*, *ii*, *iii*, *iv*, Stages in division of the same cell; i^a, cell *i* as seen under Gundlach's one-sixteenth immersion lens; *v*, a branching colony, the cells of which still retain their original connections.

Whether the characteristic properties of yeast are dependent upon the existence and manifestation of life in the plant, or are merely the result of chemical activity on the part of some principle capable of extraction in an active state, has been an intensely interesting and highly important question ever since the discovery of active constituents in plants. The most recent experiments by Büchner seem to prove that the latter is true, the enzyme *zymase* having been described by him. Since it is incapable of escaping through the pores of the cell wall, its extraction is dependent upon a process of extreme disintegration. Zymase retains its properties after extraction for only a comparatively short period, a few months being the longest time recorded.

Into the general uses of yeast it is not the design of this article to enter. It is concerned in the production of all beers, wines, and liquors, and of the common "raised" breads and cakes. As a modifier of food in these instances it has considerable dietetic importance; when mixed with a moderately thick dough, the disengagement of carbonic acid taking place throughout, fills it with innumerable minute interstitial bubbles, or makes it spongy, as the housewives say, or light. If baked in this condition these bubbles expand with the heat, making the bread still "lighter," or more porous, and in a condition for more ready disintegration in the stomach and intestine than breads made without yeast, and depending upon the vaporization of water only for their lightness. The alcohol is mostly dissipated in the baking and cooling of the bread; the cooked yeast itself is probably of no special dietetic consequence.

In medicine yeast is now scarcely used. It has been given in indigestion, dyspepsia, etc., but is of little consequence (there are yeast cells in or upon our food almost always). Dose of liquid yeast, 15 or 20 gm. (℥ ss.). It still survives to a moderate extent as a poultice (*Cataplasma Fermenti*), which is simply a thin raised dough.

Take of beer yeast, 6 fluidounces; wheaten flour, 14 ounces; water heated to 100° F. (37.8° C.), 6 fluidounces. Mix the yeast with the water and stir in the flour. Place the mass near the fire till it rises.

Yeast poultice is a light, agreeable application, and is thought to overcome the odor and reduce the decomposition of sloughing sores. It is seldom used in this country.

Revised by *Henry H. Rusby*.

YELLOW FEVER: HISTORICAL SKETCH OF THE DISEASE, ITS ETIOLOGY AND MODE OF PROPAGATION.

—HISTORY.—The remotest records about epidemic diseases in the Old World fail to show that yellow fever or any other disease presenting similar epidemiological features had ever been observed previous to the discovery of America in 1492; while in the newly discovered lands it soon became apparent that every expedition of European settlers that came to the Antilles or to the Spanish Main had to pay a heavy tribute to an unknown pestilence, during the first summers of their residence, suffering thereafter no further trouble from the climate. Was this pestilence yellow fever?

In order to answer that question Bérenger-Féraud and I, independently of each other, undertook minute historical researches, some fifteen years ago. We both came to the same conclusion: that the disease mentioned in the old Spanish chroniclers as the "peste," "contagio," or "epidemia," was no other than our modern yellow fever; and that, at the time of the discovery, it was endemic on the coast of Mexico, at the present site of Vera Cruz, as well as on the Atlantic side of the isthmus, and on the Spanish Main along the coast of Colombia and Venezuela inhabited by the Carib Indians. These warlike Indians were constantly plying across the Caribbean Sea in their canoes, and through them yellow fever appears to have been sometimes conveyed to their own Isles of Dominica, Guadeloupe, Porto Rico, and to the eastern end of Hispaniola (the Province of Higuey in Santo Domingo) which was often visited, if not held in actual subjection by that fierce Indian tribe. The disease was called "Poulicantina" by the Caribs (Bérenger-Féraud) and "Cocolitzle" by the Mexicans (see my "Epidemiologia primitiva," in Cronica Medico-Quirurgica de la Habana, Mayo 15, 1897).

The Caribs maintained in captivity upon their own isles a number of women and youths captured by them from the peaceful and even timorous tribes who dwelt upon the greater Antilles, the male adult prisoners having been disposed of to satisfy the cannibal instincts of the captors. Being born or bred in the endemic foci on the mainland, the Caribs must have been immune against the Poulicantina, just as the natives of Cuba have been hitherto against yellow fever; but the presence of the non-immune captives may have supplied the required material for the occasional development of poulicantina epidemics in the Carib Isles, and also in the Higuey district of San Domingo; and in this way the disease could readily have reached any foreigners who chanced to visit those islands. This is indeed what seems to have happened to the Spaniards, newly arrived in Hispaniola, during a long succession of summers ever since their first settlement in 1494; and to the French ever since their first attempts to colonize the Carib Isles, one and a half centuries later. The French missionaries, less reticent than the Spanish colonists had been, made no mystery of the symptoms of the epidemic disease which attacked them, and which, they said, was known in the Spanish Islands under the names of "peste" or "epidemia"; so that the identity between our modern yellow fever and the poulicantina as well as with the "peste," "contagio," "epidemia," of the Spanish colonies, could no longer be doubted, after the description of Du Tertre, who witnessed the epidemic of Guadeloupe in 1648, and Cogolludo's minute account of that of Yucatan the same year.

First Names Given by the Spaniards to the Pestilential Disease which Attacked the Spanish Settlers Newly Arrived in Hispaniola and Darien.—On the 2d of February of 1494, two months after the arrival of Columbus at Hispaniola, on his second voyage, bringing with him the first European expedition (fifteen hundred men) that ever set foot on American soil, twelve of the seventeen vessels on which that expedition had come sailed away, under command of Antonio Torres, for Spain, taking, no doubt, the route through the Canary Islands which was still followed in those days. At the port of departure where the colonists, by order of the admiral, were building the town of Ysabela, most of the men had been falling sick since the last week of January; but though many were on the sick list only few died. Critics are mostly agreed in attributing to malarial fevers the illness which attacked the men at this time, the admiral himself having been one of the sufferers. It is possible, however, that some of the fatal cases may have been yellow fever. At any rate, as the year advanced, the situation became more critical, and by the end of May, when the admiral's brother, Bartolomé Colon, arrived with three vessels laden with provisions from Spain, sickness and death had been rife among the Spanish settlers in Hispaniola, not only at the port of Ysabela, but also in the interior of the island where forts had been constructed near the gold mines. The Indians then began to run away from their masters, deserting the culture lands, perhaps in order to preserve themselves from a contagion with which they were already familiar; but the Spaniards attributed their dispersion to a preconcerted plan for starving the foreign invaders out of their country by not planting at the proper season the vegetables upon which the inhabitants were most dependent for their subsistence. Oviedo attributes to this action of the Indians the great mortality which followed. From two-thirds to one-half of the Spaniards died, but innumerable were also the deaths among the Indians themselves, whose cadavers lay strewn in the fields, producing, says the chronicler, a most horrible and pestilential stench. Columbus, in the mean time, had been absent from the island since the end of April, exploring the coasts of Cuba and Jamaica, and intending also to visit Porto Rico. About the middle of September, on his way from Jamaica to Porto Rico, he came close to the shore on the south coast of Hispaniola, holding intercourse with the Indians and landing nine men of his crew to convey information about his own movements to his people at Ysabela, across the island. He was detained by a severe hurricane during seven or eight days in a narrow pass between the coast and the islet of Saona, close to the Higuey district. On the 25th or 26th of September, as he was proceeding toward Porto Rico, he was suddenly attacked by a grave illness, which deprived him of his senses and so much alarmed the crew that they turned from their intended course and brought the admiral and the other two vessels back to Ysabela, where they arrived on the 29th. He continued several days ill, and had a long convalescence, probably prolonged by a return of his malaria infection, as often happens in Cuba in the convalescence of yellow fever. In a letter which the admiral wrote to the King, he states that his illness on that occasion had been a "modorra pestilencial," probably the name which Dr. Chancas, the physician attached to the expedition, had given to the disease which had been causing so many deaths on the island since the admiral's departure in April. This same pestilential disease appears also to have been carried from Hispaniola to the Canary Islands, either by the vessels of Antonio Torres, or, more probably, by the three which returned to Spain after having landed D. Bartolomé Colon at Ysabela; for Humboldt and Bonpland inform us that "what remained of the Guanches on the Island of Teneriffe perished mostly in 1494, in the terrible epidemic called the 'Modorra." Though every subsequent expedition which landed at Hispaniola lost one-third or more of heir contingent from the same pestilence during the irst summers of their residence on that island, the chroni- lers, warned by the panic which had been created in pain by rumors of the first epidemic, were silent as to he name and symptoms of the disease, always attribut- ng the great mortality to the bad quality of the food nd to the change of climate. But in 1514, when Pedra- ias Davila landed at Darien with a splendid expedition, mong whom were the Chronicler Oviedo and Andagoya, oth of whom had lived in former years in Hispaniola, a rrible epidemic broke out among the newcomers, caus- g seven hundred deaths in one month, and each of the bove-mentioned authors declares that the cause of it was e "modorra sickness"; adding that after the new- omers had gone through that ordeal, the climate proved s salubrious to them as that of Spain. The name of modorra" was, however, soon abandoned, probably ecause the stupor or coma which characterizes some articular epidemics of yellow fever (see Cornillac, l. 1875, p. 423) was found to be a less constant symp- m than Dr. Chancas had imagined. In subsequent ars the uncompromising terms of "peste," "pestilen- a," "epidemia," "contagio," were substituted, and con- nued in use till the end of the seventeenth century.

The names of vomito negro and yellow fever were first ven to the disease in the early part of the eighteenth ntury. In 1758, a surgeon of the Spanish navy, Dr. sef Gastelbuondo, who had settled in private practice Cartagena de Indias, published a book on the "vomito gro," stating in his preface that he had been studying disease and investigating its causes during the pre- us forty years, and had performed several autopsies. range to say, he attributes the disease to the same uses which had been constantly invoked by the early anish colonists of the two previous centuries, namely, the change of climate and to the poor quality of food which the newcomers were unprepared. Other nes such as typhus amaril, typhus ictérode, hæmo- tric pestilence, malignant remittent, putrid fever, ., continued, however, to be used conjointly with that "vomito negro," yellow fever, fièvre jaune, febre lla, till the commencement of the nineteenth century.

uring the first two hundred years after the discovery America the ports of Santo Domingo, Cartagena de ias, Porto Bello, Darien, Vera Cruz, where the "flotas Indias" brought each year, during the summer nths, a large number of non-immunes from Spain, yel- fever assumed the character of a permanent endemic, le on the Island of Cuba, owing perhaps to its cooler nate and to the fact that its communication with Spain less direct, the disease obtained a permanent foot- l only in 1761, after the occupation of Havana by the lish and the subsequent opening of Cuban ports to eral commerce. Since that time and until 1901 Ha- a has been considered a constant menace of yellow- r infection for the United States and for European s. Rio de Janeiro, Brazil, on the other hand, has me an endemic focus only since 1850.

ew Orleans also was at one time considered an en- ic focus of yellow fever, not less than forty-eight emics having been recorded in the first sixty years of nineteenth century; but the success which has fol- d the observance of strict quarantine measures after civil war plainly shows that the infection of that had in reality been derived from repeated importations from Vera Cruz, Havana, Central America, or from the West Indies. The propensity of yellow fever to spread into neighboring countries, along the lines of traffic, and to be carried in ships to far distant ones when certain climatic and topographical conditions are realized, has been verified again and again, causing innumerable victims as well as serious financial distress, and spreading terror over large areas in North and South America, on the western coast of Africa, in the Canary Islands, in the southwest part of Europe, and at times reaching as far north as Quebec and Swansea, and as far south as Montevideo and Buenos Aires. The climatic and topographical conditions to which reference has been made are essentially those which are compatible with the existence and functional activity of the insect which, as will be seen, assumes the rôle of a natural transmitter of the yellow-fever infection; the principal ones being the prevalence of temperatures between 70° and 90° F., low levels above the seaboard, proximity to the sea or to watercourses, and protection from strong winds. There is, however, another condition which must be inferred by reason of the geographical distribution of the disease, but for which no satisfactory explanation has yet been offered. I refer to the fact that while yellow fever is so frequently carried over the waters of the Atlantic Ocean, and, very exceptionally, far into the Mediterranean Sea, it is a remarkable fact that there is no record of the disease having ever been conveyed over the waters of the Pacific Ocean beyond the western coast of America, where epidemics have often occurred. Whether or not this fortunate state of things will continue after the Panama canal is thrown open, must be a matter of conjecture; but the bare possibility that it might not so continue should be borne in mind and act as a stimulus for all nations interested in the matter to urge the stamping out of yellow fever from the Caribbean Sea and the Gulf of Mexico, as well as from the western shores of America, before free communication is established between the waters of the two oceans in the very heart of the yellow-fever territory *par excellence.*

For a detailed account of yellow-fever epidemics in different countries the readers must be referred to Bérenger-Féraud's valuable chronology of the disease ("La Fièvre Jaune," Paris, 1890), and to Dr. G. M. Sternberg's article in the first edition of this HANDBOOK.

ETIOLOGY AND MODE OF PROPAGATION.—In the first edition of this HANDBOOK, Dr. G. M. Sternberg expressed himself in the following terms regarding the etiology of yellow fever.

"As to the nature of the *specific cause* of the disease there can scarcely be two opinions. The present state of science justifies the belief that it is a living micro-organism, and facts relating to the origin and extension of epidemics show that, as in cholera and in typhoid fever, this micro-organism is capable of development outside of the human body under conditions which will be discussed hereafter. Unfortunately, the present state of science does not enable us to give an account of the deadly microbe which we assume to be the cause of the disease under consideration. We know to-day the morphological and physiological characters and the habitat, within the body of an infected individual, of the specific cause of cholera, of typhoid, and of relapsing fever, but the researches made up to the present time have failed to demonstrate the 'germ' of yellow fever" (REFERENCE HANDBOOK OF MEDICAL SCIENCES, Vol. VI., 1887).

My tetragenus febris flavæ (M. tetragenus versatilis Sternberg) fared no better under Dr. Sternberg's keen criticism than did the *germs* of Freire, Carmona, or Gibier, nor shall I at present renew my claim as to its etiological significance; but I think it worth while recording the following remarkable coincidence. In 1895, in a paper on "Tetracoccus Versatilis," which was published in the *Edinburgh Medical Journal* (December, 1895), I called attention to the curious circumstance that pure cultures of my tetragenus, which had been filtered through Kitasato filters, had on two occasions given evidence that some of the tetragenus germs had passed through the pores of the filter; while in 1901, in the last experiments performed by the United States Army Board, we are informed that the blood serum of a yellow-fever patient, after being passed through a Berkefeld filter, gave evidence that the germ had passed through the filter, for positive results were obtained when the filtrate was injected into non-immunes, and Drs. Reed and Carroll infer that the said germ must be ultra-microscopic (see the article published by Drs. Reed and Carroll in *American Medicine*, February 22d, 1902, p. 304). Should the fact be confirmed that my tetragenus possesses ultra-microscopic spores besides the coarser forms which it develops in our artificial culture media, most of the objections which have been raised against its etiological significance would fall to the ground.

In 1897 Dr. Sanarelli discovered in his cultures from yellow-fever material collected in Brazil a new bacillus which he still considers the specific germ of the disease. This discovery attracted a good deal of attention, having been confirmed by some other observers, while others again strenuously denied that it had any etiological significance. The unquestionable competence of the discoverer and his previous good record at the Institut Pasteur added considerable weight to his claim. A final verdict, however, was given against him after it was averred that his bacillus icteroides never developed in any of the bouillon tubes that were planted, by Drs. Reed, Carroll, and Agramonte, with samples of yellow-fever blood which, inoculated into non-immunes, invariably reproduced the disease. I believe, however, that the bacillus of Sanarelli may be one of the promoters of the secondary infections which characterize the hæmogastric forms of yellow fever, and in that capacity it may yet be found to constitute an important factor in the development of the worst complications which are apt to occur in the course of an attack of yellow fever.

However much it may be regretted, that up to the present day the specific germ of yellow fever has not been identified, so that the diagnosis of some abortive or atypical cases must often be considered problematic, it is, however, a great source of satisfaction that we positively know the manner in which the disease is transmitted in nature, and that this knowledge enables us to control with great success its propagation and to stamp it out, as has been done in Havana during the last sixteen months.

Discovery of the Yellow-fever Mosquito.—Apart from the historic interest which the matter might afford, I think it proper to acquaint the reader with the arguments which led to the discovery of the particular mosquito by which yellow fever is transmitted, inasmuch as, considered from an *a priori* point of view, those same arguments should prove more convincing than when they are presented merely as a sequel to the demonstration.

In 1880, after receiving the valuable report given out by Prof. Stanford Chaillé as president of the Havana Yellow-fever Commission of 1879, I undertook a careful revisal of all the facts which had been collected since 1853 in the United States, and arrived at certain conclusions which are here summarized in the form of propositions, and which afforded a solid foundation for my future investigations.

Proposition A. Though yellow fever must be considered to be a germ disease, it is transmissible only under certain topographical and climatological conditions which are realized at all seasons of the year only in certain localities along the Atlantic shores of tropical America, where the disease is considered endemic, and of which Havana might be considered a type.

Proposition B. Even within the infected foci, the disease is apparently not contracted through contact with the patient or his secretions, nor by breathing the air of the sick-room, nor by the use of contaminated food or drinks.

Proposition C. The pathological lesions pointed out by Crevaux, Gama Lobo, and other competent observers, in the walls of the blood capillaries of yellow-fever cadavers, and the hemorrhagic tendency which, as a rule, develops in the course of the attack, even in mild cases, suggested the idea that the mesoblastic tissue from which the vascular endothelium is formed might prove to be the most appropriate source from which the infective material could be obtained.

From proposition A, I had inferred that, for the production of a case of yellow fever, a third factor was required besides the yellow fever patient and a person susceptible to the infection—a factor which, though indispensable for the transmission, might exist independently of the patient and of the disease. It should, however, be essentially dependent for its existence and for its functional activity on the topographical and climatological conditions which favor the transmissibility of yellow fever.

From proposition B, I inferred that the only unexplored channel by which the virus or germ might prove pathogenic for human beings must be by a process of inoculation.

From proposition C, I surmised that in order that the inoculation should prove effective, the infectious material might be obtainable only from the blood or from the walls of the blood capillaries of a yellow-fever patient, and might require also to be inserted into the capillaries of a non-immune.

I was thus led to conclude that the transmission was effected through the agency of some blood-sucking insect which was peculiar to yellow-fever countries, and which was able to retain upon its mouth parts the living germ so as to inoculate it afterward into those whom it chanced to bite. In searching for such an insect I came across the day mosquito of Havana (culex mosquito Desv., Stegomyia fasciata Theo.), in which I had observed certain peculiarities in the manner of laying its ova, and in its readiness to renew its bites whenever the digestion of a previous meal of blood had been completed, both of which peculiarities seemed to differentiate it from other species of gnats and to make it particularly well suited for the purpose of reproducing a disease in an epidemic form. Upon investigation I found that this insect was benumbed and unable to bite under the influence of temperatures of 15° C. (59° F.), at which degree of cold epidemics of yellow fever were known to cease in New Orleans, in Rio Janeiro, and in Havana; and also that after being kept for a while in a rarefied atmosphere corresponding to altitudes of four thousand to six thousand feet, at which elevation yellow fever is intransmissible, the insect lost to a great extent the power of driving its sting into the flesh.

My next step was to submit my theory to an experimental test by applying to non-immunes mosquitoes of that species which had been made to bite, two or three days before, a severe case of yellow fever. Among twenty non-immune soldiers who were set apart and kept under observation during two months, five were on different dates bitten by a mosquito which had been contaminated in that manner. Three of the five were taken sick after their inoculation, one after fourteen days with a mild but characteristic attack of albuminuric yellow fever, two were attacked on the fifth day after the inoculation with an abortive form of yellow fever, while neither of the other two showed any symptoms characteristic of the disease. None of the fifteen who had not been inoculated suffered any similar attack of fever during the two months that they remained under observation. After the lapse of four years I ascertained that none of my five inoculated soldiers had been reported again as suffering from yellow fever.

During the next twenty years I continued to perform that mild form of inoculation, my object being to ascertain whether or not some degree of immunity might thereby be obtained even when no immediate pathogenic effect had followed the inoculation. The principal data concerning each of the mosquito inoculations that were performed either by me or by my collaborator, Dr. Claudio Delgado, have been set down in Table I., so that the reader may judge for himself and draw his own conclusions. Two of the inoculations (No. 3 and No. 104 of

Yellow Fever.

TABLES OF MOSQUITO INOCULATIONS PERFORMED IN HAVANA.

Abbreviations which are used in these tables:

"eph."	Ephemeral fever without characteristic symptoms.
"Abort."	Abortive yellow fever, with albuminuria.
"abort"	The same without albuminuria.
"N-a"	Non-albuminuric yellow fever with well-marked fever curve and other symptoms.
"n-a."	The same with milder symptoms.
"y-f."	Yellow fever about which particulars are not given, but not fatal unless so expressed.
"Alb."	Regular albuminuric yellow fever.
"alb."	The same of mild type.
"Hg."	Hæmogastric yellow fever, with black or bloody vomit or melæna, of fatal termination.
"hg."	The same, not fatal.
"s."	Severe.
"f."	Fatal.
"m."	Mild.
"vm."	Very mild.

Symbol of contamination. The figures to the left of the oblique stroke express the days that have elapsed since the insects have bitten the infecting patient. To the right of the oblique stroke are expressed, in abbreviation, the type of the disease, and, in Roman numerals, the day of the attack when this patient was bitten.

my former tables) have been omitted, because the mosquito in those two cases had not previously bitten any yellow-fever patients.

I was fully aware, at the time, of the shortcomings in my mode of proceeding, the principal ones being: 1. That I had neither leisure nor other facilities for breeding my mosquitoes from the ova or from the larvæ, but had to rely on the outward appearance of the winged insects and on the conditions of the locality where they had been caught, in order to exclude as far as possible the chances that the insects might have been already infected at the time when they were caught. 2. That with the exception of one case (No. 9 of Table I.), in none of my cases had I been able to exclude altogether the possibility that the inoculated person might have been infected from some other source after my own inoculation. 3. That I could not assume the responsibility of attempting to produce severe, perhaps fatal experimental attacks by applying more than two or three recently contaminated insects at one time, or even one mosquito whose contamination dated back from several days or weeks, by either of which processes I had assumed that a dangerous experimental result might follow.

The outcome of my continued study had led me, in 1898, to the following conclusions:

1. That the germ of yellow fever is only pathogenous for human beings when introduced by inoculation. 2. That the regular process by which the inoculation of the germ is accomplished, in nature, is through the bites of the culex mosquito (Stegomyia fasciata Theo.), the insect having previously become contaminated through the act of biting a yellow-fever patient within the first five days of his attack. 3. That although the bites of a recently contaminated mosquito can produce at most only a very mild attack of yellow fever, or simply confer latent immunity without eliciting any obvious pathogenic manifestation, the bites of the same insect, when its contamination dated back from several days or weeks, might produce severe or fatal attacks. 4. That the yellow-fever mosquitoes, after they have once become contaminated, retain the power of inoculating the disease during the rest of their lives. 5. That yellow fever might be stamped out of Havana by just such a method as the one which was adopted by Major W. C. Gorgas, with signal success, in 1901.

EXPERIMENTAL DEMONSTRATION OF THE MOSQUITO THEORY AND NEW FACTS BROUGHT TO LIGHT BY THE UNITED STATES ARMY YELLOW-FEVER COMMISSION* IN HAVANA.

A most eventful period in the history of yellow-fever investigation opened in the month of July, 1900, when the yellow-fever commission, which had been sent from Washington to study that disease in Havana, undertook to investigate the mosquito theory of yellow-fever transmission with a brood of those insects developed from ova of the culex mosquito (Stegomyia fasciata Theo.) which I had preserved and placed at their disposal.

In the course of twenty days, from August 11th to 31st, 1900, they tried the mosquito inoculations upon eleven non-immunes. The results were negative in their first nine attempts, which consisted in applying to a non-immune one or two insects which had bitten a case of yellow fever (mostly of a mild type) two, three, four, five, six, eight, or thirteen days before biting the non-immune. Their next two attempts, however, proved successful beyond their expectations. The first of these was made upon a member of the commission, Dr. Carroll, who applied to his own arm a mosquito which had bitten four yellow-fever patients (two of them severe cases) two, four, six, twelve days before the inoculation. Three days and seven hours after the bite of the contaminated mosquito, Dr. Carroll was taken sick with a severe attack of well-characterized albuminuric yellow fever (see No. 1, Table II.). The second successful inoculation was obtained upon a non-immune American, who offered himself for the trial. He was bitten by four mosquitoes which, between them, had previously bitten ten yellow-fever patients (two of them fatal and two severe ones) at different intervals varying between two and sixteen days before the inoculation. This American was attacked at the end of six days and two hours with high fever, and presented all the characteristic symptoms of yellow fever, the albuminuria and jaundice continuing till several days after convalescence (No. 2 of Table II.).

---

* This commission was composed of Walter Reed, M.D., Surgeon, U. S. A., James Carroll, M.D., and A. Agramonte, M.D., Jesse W. Lazear, M.D., Acting Surgeons, U. S. A. Dr. Lazear died of yellow-fever while Dr. Carroll was barely convalescent of his experimental attack. He attributed his own attack to the circumstance that during a visit to the yellow-fever ward of Las Animas Hospital, four or five days before he was taken sick, he had noticed a mosquito biting his hand, and being already a believer in the mosquito theory he had refrained from driving away the insect and had allowed it to fill itself completely in order to watch the result.

TABLE II.—SUCCESSFUL MOSQUITO INOCULATIONS BY THE UNITED STATES YELLOW-FEVER BOARD, 1900 AND 1901.

13	Sp. f.	16 September, 1901	4	53/f., iii. 34/f., ii.	3 days	September 10: Alb.
14	Sp. g.	9 October, 1901	8	18/(case 13), ii.	3½ days	October 13: alb. tr.

In neither of these two cases had the inoculated subjects been isolated or kept under close observation until the first symptoms of the attack had declared themselves; but the circumstance that their insects were home-bred, that the attack had commenced within the classical limits of the yellow-fever incubation, and that the symptoms were very characteristic, convinced them not only of the fact that the mosquito was indeed the transmitter of the disease, but also, by reason of their first negative results, that an interval of at least ten or twelve days must elapse after the insect has bitten a yellow-fever patient before it acquires the faculty of inoculating the disease. They decided, therefore, to act in accordance with this principle in all their future experiments.

After delivering their preliminary report with a minute account of their two successful inoculations, the same commission returned to Havana with instructions to carry out to a close the demonstration of the important question involved: Whether or not the Stegomyia mosquito is the natural transmitter of yellow fever. For this purpose they were provided by Gov.-Gen. L. Wood with ample means, and permitted to repeat their mosquito inoculations upon any non-immune who, after being informed of the risks, should consent to be experimented upon.

After a careful preparation of the premises and the adoption of many ingenious devices to exclude chances of error, the commission started a series of mosquito inoculations which, under the circumstances in which they were performed, left no room for a doubt as to the fact that the experimental attacks which followed the inoculations could be attributed only to the bites of their contaminated mosquitoes.

By adhering to the rule of using in their experiments only mosquitoes having more than ten or twelve days of contamination, and which had been kept at summer temperatures (80° to 82° F.), they had no difficulty in obtaining well-marked results, the failures having been the exception. They were thus able to contaminate their fresh mosquitoes from previous experimental cases of their own, and, on some occasions, to confirm a doubtful clinical diagnosis by applying to a non-immune mosquitoes which had bitten the patient.

The fourteen successful mosquito inoculations obtained by the Army Board during the years 1900 and 1901 have been tabulated for future references (see Table II.), leaving their other valuable experiments with the injection of yellow-fever blood, and others also for the purpose of demonstrating that fomites and air-borne germs have no share in the propagation of the disease, to be considered after I have completed the record of all the inoculations with mosquitoes that have so far been published.

The following series of Prof. John Guiteras will show the advantage of including in such reports not only the successful experiments, but also the negative ones.

During the spring and summer of 1901 Professor Guiteras, being in charge of the Experimental Station at Las Animas Hospital, undertook to ascertain whether the mosquito inoculation could be safely used as a means of conferring immunity upon new comers. His experiments at Las Animas were performed according to the rules set down by the Army Board, and the same precautions were taken to exclude sources of error. In the course of nine months, from February to October, 1901, he performed forty-nine inoculations upon twenty-three subjects who were supposed to be non-immunes, but two of them apparently were not. Nine of the forty-nine attempts were followed by a well-marked attack of yellow fever within three to six days after the bites of the infected mosquitoes. The first successful inoculation (No. 2, Table III.) was performed with a mosquito which had been presented to me by Dr. Carroll, of the Army Board, and which had bitten only once an experimental blood case (No. 4, Table IV.) about nine hours after the invasion. This insect was applied on the 23d of February to a non-immune Spaniard who was taken sick on the 26th at midnight with a mild but characteristic attack of albuminuric yellow fever (No. 2, Table III.).

Seven of Dr. Guiteras' successful inoculations were obtained with mosquitoes which had been contaminated from a particular patient (Alvarez), while other mosquitoes which had bitten different yellow-fever patients coming from the same locality, and who had been attacked about the same time as Alvarez, all gave negative results, even when applied to subjects who afterward succumbed to the Alvarez mosquitoes. The attack in the infecting patient (Alvarez), though severe, had not been fatal; yet the insects which had bitten him only once acquired such a virulent contamination that out of

Case 5 received an injection of filtered serum on the 15th and another of fresh blood on the 22d; opinions being divided as to which of the two injections was the successful one, the case has been recorded with a query, both in this table and in the following one (No. 3 ? T. V.).

nine persons to whom they were afterward applied seven were attacked with severe yellow fever, and three of them proved fatal. A mosquito which had been fed from the arm of Dr. Guiteras' first experimental case (No. 2, Table III.) gave a negative result when applied after seventeen days, and again eight days later, with twenty-five days of contamination, to Miss Maas (No. 4, *a* and *b*, Table III.), who died three months later from the bites of two of the Alvarez mosquitoes (No. 4, *f*, Table III.). Another mosquito which had bitten the patient upon whom Dr. Carroll had experimented with unheated defibrinated blood (No. 1, Table VI.), was applied, twenty-six days after biting this patient, to a non-immune (No. 21 *a*, Table III.) with a completely negative result. Finally, three mosquitoes which had bitten Dr. Guiteras' last successfully inoculated patient (No. 20, Table III.) three days and five hours after the first onset of the fever, were applied at the end of three, sixteen, and twenty-three days respectively to three non-immunes (No. 22, 23 *a* and *b*, 21 *b*), and the result was negative in all three. These results evidently prove that not all the Stegomyia mosquitoes that bite genuine yellow-fever patients become infected, even when all the conditions set down by the Army Board are complied with. This had already been inferred by Dr. Reed after witnessing an instance in which the simultaneous bites of twelve mosquitoes which had bitten a mild experimental case (No. 8, Table II.) failed to transmit the disease to a person considered non-immune, although the injection of 2 c.c. of blood drawn from the same patient had produced a characteristic attack in another non-immune (No. 1, Table IV.). The only hypothesis which affords a satisfactory explanation of these apparent anomalies seems to be that many of the natural or experimental cases of genuine yellow fever, but principally among those of a mild type, are due to the introduction of a limited number of germs which, having taken root, as it were, in some undetermined region of the body, establish a localized infection; and that the general symptoms of yellow fever which follow are elicited by the soluble toxins conveyed through the blood circulation. Under these circumstances mosquitoes fed from the germ-free peripheral blood would not become infected, while a direct injection of the blood itself, saturated with toxins, might produce a purely toxæmic attack of yellow fever insusceptible of further reproduction.

The importance of this hypothesis will be better appreciated after one has gone over the interesting and highly instructive experiments which were performed by the Army Board with blood freshly drawn from the general circulation of yellow-fever patients on the first or second day of their attack.

Their first series consisted in injecting subcutaneously from 0.5 to 2 c.c. of blood drawn from a vein in the arm of a yellow-fever patient. They have reported five successful experiments of this kind (Table IV.), but the fifth, as will be explained farther on, belongs more properly to their other experiments with filtered blood serum (Table V.), and has for that reason been included in both tables, with a query appended to each.

The conclusions of the Army Board regarding their blood inoculations were expressed in the following terms: "First, that the parasite is present in the blood—at least during the early stages of the disease; secondly, that the passage through an intermediate host is not essential in the life cycle of the parasite. Thus yellow fever is analogous to the malarial fevers in that it may be produced either by the bite of a certain species of mosquito or by injection of blood taken from the general circulation." (*American Medicine*, July 6th, 1901, p. 16.)

Another very important investigation was carried out by the Army Board with blood drawn from a vein at the bend of the elbow of a mild experimental case (No. 14, Table II.). This blood, amounting to 65 c.c., was placed in a sterile test tube and set aside during five and one-half hours in the refrigerator. At the end of that time 19 c.c. of the supernatant, slightly blood-stained serum was pipetted off into another sterile tube, and after diluting it with an equal quantity of sterilized distilled water, it was filtered through a Berkefeld filter, previously tested and sterilized. Ten and a half hours after the blood had been drawn from the patient, 3 c.c. of the filtrate, corresponding to 1.5 undiluted serum, was injected into two American non-immunes (Nos. 1 and 2, Table V.). Both fell sick, after an incubation of a little over four days, with a mild attack of yellow fever. One showed a trace of albumin on the fourth day, but the other had none at all during his entire illness. The latter was, in fact, a type of what I have elsewhere termed the non-albuminuric abortive form. Three and a half hours after the inoculations of these two Americans, a third one (No. 3, Table V.) was likewise injected with the same quantity of the filtered serum, which by that time had been kept fourteen hours in the refrigerator. This inoculation was thought to have been a failure, as no reaction had been observed at the end of the seventh day, and the same subject was again utilized for another experiment. He was injected, at the commencement of the eighth day since his previous injection with filtered serum, with 1.5 c.c. of blood freshly drawn from the arm of the first American (No. 1, Table V.) on the fourth day of the attack. The object of this blood injection had been to ascertain whether the experimental attack in No. 1 (Table V.) should be attributed to soluble toxins contained in the filtered serum, in which case the second injection must be expected to give a negative result, or to the presence of ultra-microscopic germs which had passed through the Berkefeld filter, and which, having multiplied after being inoculated, would enable the disease to be reproduced through the injection of the patient's blood. This well-conceived experiment was, however, deprived of its significance by the circumstance that, not having at hand a fresh non-immune, it was performed upon a subject who might still be under the influence of a previous experiment. In point of fact, exactly eight days after this third American had received the injection with filtered serum, and just twenty-four hours after his injection with the fresh blood (No. 3, Table V., and No. 5, Table IV.), he was attacked with a mild form of yellow fever, showing a trace of albumin on the fourth day. The question as to which of the two injections had been the successful one rests, therefore, on the greater probabilities of an incubation period of eight days rather than of one of twenty-four hours. The experimenters decide in favor of the latter, but I cannot agree with them on that decision, for there is no reliable precedent for such a brief incubation as twenty-four hours in the records of either natural or experimental cases, while there are examples of both kinds regarding an incubation of eight days. Dr. Carter, in his valuable paper on that subject (New York *Medical Record*, March 9th, 1901, p. 366), gives the particulars about four members of a family who at different hours of the same day had gone from a non-infected house where they lived to an infected one at a short distance from their home, and they were all taken sick with yellow fever in the course of the eighth or ninth day after that visit, while a fifth member of the family who had not accompanied the others in their visit to the infected house, only took the disease several weeks later. As an experimental case in point, I can quote the only one (No. 9, Table I.) of my one hundred and two inoculated subjects about whose isolation from other sources of infection I had a reliable guarantee. With regard to the mosquito which I had used, it was not a home-bred insect, so that I have not the same certainty that it might not have bitten a yellow-fever patient before it was caught; but at any rate, I do know that the only source of infection to which the person had been exposed was the bite of my infected mosquito. He was bitten on the 17th of August, 1883 (hour not recorded), and was taken sick on

the 26th at 11:45 A.M., with a characteristic attack of non-albuminuric yellow fever, only a doubtful trace of albumin having been obtained in the night of the fourth day. There were hawking up of bloody phlegms, bleeding from the gums on pressure, yellowness, and the spontaneous defervescence on the seventh day, and his immunity was subsequently proved by more than twelve years of residence in Havana. In this experimental case, therefore, the incubation was between eight and nine days.

Until some more decisive experimental proof can be given, I must therefore adhere to my belief that the pathogenic effects which followed the injection of filtered blood serum in the experiments by the Army Board were due to the soluble toxins contained in that serum rather than to the hypothetical ultra-microscopic germ invoked by the experimenters. I believe, furthermore, that those experiments confirm my opinion about my own experimental cases (see Table I.), and that some of the pathogenic effects, which were observed after a few of my inoculations with recently contaminated mosquitoes, may have been due to the direct inoculation of human germs which had been retained upon the setæ of the insect's sting; these germs having found an appropriate nesting-place in some region of the body of the inoculated person and producing through their toxins mild non-infectious attacks of yellow fever, such as I have mentioned in connection with Dr. Guiteras' experiments at Las Animas.

While the inoculations with filtered serum were being carried on by the Army Board, the residual blood which had remained in the test tube after the supernatant serum had been pipetted off was mixed with 19 c.c. of sterilized distilled water and beaten up with a sterilized egg-beater, to remove most of the fibrin. This mixture may be supposed to have differed from the original 65 c.c. of blood, in that it would be poorer in soluble toxins by the quantity contained in the 19 c.c. of supernatant serum which had been pipetted off, but richer in living germs, for these would naturally gravitate, together with the red globules, to the bottom of the test tube. Fifteen and a half hours had elapsed since the blood had been drawn from the patient (five and a half in the refrigerator and ten at room temperatures) when they injected 0.75 c.c. of the above mixture into a non-immune Spaniard who was attacked, at the end of five days and two hours, with a mild but characteristic yellow fever showing a trace of albumin on the fourth day. In the mean time another portion of the same blood mixture was subjected during ten minutes to a heat of 55° C., and of this heated portion, after it had been cooled down, 1.5 c.c. were injected into three non-immune Americans, with a completely negative result, "no rise of temperature nor other symptoms of ill-health having followed the injection."

The outcome of these important experiments seems to be that the yellow-fever germ is killed by ten minutes' exposure to 55° C., but is not entirely deprived of its virulence by exposure to the cold of a refrigerator (presumably between 40° and 50° F.) during five and a half hours, nor by being kept *in vitro* fifteen and a half hours after having been drawn from the human subject. The soluble toxins contained in the filtered serum, on the other hand, appear to lose some of their virulence when kept beyond ten hours in the refrigerator; but nothing is known about their susceptibility to heat.

The original finding of the Army Board that through the bites of the insect variously named Culex mosquito Desv., Culex fasciatus Fab., Stegomyia fasciata Theo., experimental attacks of yellow fever can be produced almost at will has now, therefore, been established beyond the possibility of a doubt. But the Board had yet another task to fulfil, namely, to show that the disease is not also transmitted by any of the other modes of contagion which had formerly been invoked. For this purpose they instituted two very convincing experiments. One consisted in partitioning a room, by means of mosquito-proof wire netting, into two compartments, so that a certain number of contaminated mosquitoes which had been introduced into one of the compartments could be seen from the other side of the screen, but could not cross the barrier. A non-immune was then introduced on three occasions on two successive days into the compartment with the contaminated insects, while at the same hours two other non-immunes occupied the compartment on the other side of the screen. At the end of three days and twenty-three hours from his first visit to the mosquito compartment the first of these non-immunes was taken sick with a characteristic attack of yellow fever, while neither of the two who had been in the mosquito-proof compartment experienced the slightest inconvenience.

The other experiment consisted in accumulating in a mosquito-proof building constructed *ad hoc* all sorts of garments, bedding, rags, and refuse which had been soiled or used by yellow-fever patients or by their discharges, under the worst imaginable conditions, and allowing three non-immunes not only to enter that building, but to handle the objects, and to unpack them out of the boxes in which they had been preserved, to sleep in the soiled beds, etc., during twenty successive days. This performance was again gone through by two other couples of non-immunes during the two following periods of twenty days, and yet none of the seven who were thus exposed suffered the slightest disturbance in their health.

In order to try whether the local influence had contributed to these negative results, Major J. Ross, United States Navy, as director of Las Animas Hospital, repeated the same experiment some months later at this hospital, and the results were equally negative.

The universal conviction which has now been reached as to the fact that the mosquito does transmit yellow fever has given rise to the suggestion that other blood-sucking insects should also be able to do so. That this is not the case must be directly inferred from the circumstance that most of the blood-sucking insects, apart from the Stegomyia fasciata (Culex mosquito Desv.), are common to localities where yellow fever is transmissible, and to others where it is not transmitted from the sick to the healthy. In point of fact the difficulty in the study of yellow-fever etiology has not been to find an agent which should transmit the disease indiscriminately, but, on the contrary, to account for the fact that the disease has a very limited geographical distribution, and that its propagation is markedly affected by local conditions which are not known to affect in an equal degree any other blood-sucking insect but the Culex mosquito.

Deductions from the Experimental Facts that have been Recorded.—1. Only two ways are known by which yellow fever can be experimentally transmitted from a yellow-fever patient to a non-immune: one is through the bites of Stegomyia mosquitoes which have previously bitten a well-marked case of yellow fever within the first days of his attack, and which have been kept at summer temperatures (80° to 82° F.); and the other through the injection of blood or blood serum collected from a yellow-fever patient, also within the first days of his attack. In nature, only the first of these processes can occur.

2. Other modes of infection through fomites, both while fresh and after having been kept during several months, have proved ineffectual as a means of reproducing the disease.

3. While severe cases of yellow fever appear, as a rule, to be infectious for yellow-fever mosquitoes that have been kept at summer temperatures, not a few of the mild cases seem to be incapable of infecting those insects, even when the injection of blood collected from the same patient does occasion a mild attack.

4. The occurrence of attacks of yellow fever which cannot infect mosquitoes suggests a localized infection in some undetermined region of the body, within the boundaries of which the germs remain confined. The general symptoms would then be due to the soluble toxins conveyed through the general circulation, so that an injection of this sterile blood, saturated with toxins, might yet develop a purely toxæmic attack insusceptible of further reproduction, while mosquitoes fed with the same blood would not become infected.

5. Non-infectious forms might follow the bites of recently contaminated mosquitoes, when the live germs retained upon the setæ of the insect's sting are deposited in the wound inflicted with its next bite, and find an appropriate nesting place in which a local infection may be originated.

6. The more acute course observed in the experimental cases produced with the blood injection, as compared with those resulting from the bites of moquitoes, may be due to the fact that with the former not only the live germ, but also the soluble toxins are injected, while the mosquito bite cannot be expected to convey any of the human toxins.

7. Table VI. shows that the yellow-fever germ is killed by ten minutes' exposure to a heat of 55° C., but not by exposure to low temperatures in a refrigerator during five and a half hours, nor by being preserved in vitro during fifteen hours. Table V., on the other hand, suggests that the soluble toxins lose some of their virulence when they have been kept in vitro beyond ten hours at temperatures between 40° and 50° F. (in a refrigerator).

8. The immunity acquired by foreigners after long residence in yellow-fever countries, without ever having suffered an attack of the disease, is probably due to repeated inoculations with recently contaminated mosquitoes, such as I have recorded in Table I.

Distinctive Features and Habits of the Yellow-Fever Mosquito.—The yellow-fever mosquito is the regular day mosquito by which all the houses in Havana are infested during the summer season, and even during winter some are habitually seen flying about and ready to bite whenever the temperature rises above 75° F. It remains hidden or asleep during the night hours unless disturbed in its rest by the admission of artificial light; but is wide awake, on the contrary, from daybreak till night-time. They are more abundant, however, at some hours than at others.

The yellow-fever mosquito has been included among a group of gnats variously named by their discoverers and some of which present more or less marked differential characters, but having in common the peculiar scale arrangement upon the nape and scutellum that characterizes Theobald's new Stegomyia fasciata species. Without calling into question the scientific grounds for this classification, it may be doubted whether all the members of the group possess the faculty of reproducing yellow fever, inasmuch as the regular habitat of yellow fever is confined to the intertropical zone of the Atlantic ocean, while the geographical distribution of the entire Stegomyia fasciata species is said to extend over almost all the lowlands of the tropical and intertropical belt around the globe. The only variety of that species which has so far proved capable of transmitting yellow fever was named Culex mosquito by Robineau Devoidy and agrees in all respects with Ficalbi's description of his Culex elegans. The characters by which, as a tyro entomologist, I was able to differentiate it from the night mosquito of Havana, and also from another day mosquito which occasionally makes its appearance in the same city, were the following ones: Its graceful form and agility of movements; dark gray, sometimes almost black color of its body with silver or snow-white ornamentation; white rings around the five last joints of its hind-legs—three upon those of the middle legs, and two upon the front ones; ventral segments of the abdominal rings of a dirty white; sides of the abdomen presenting a double row of white dots; sides of the thorax ornamented with several white patches of irregular outline; front view of the thorax from above presents a combination of white lines figuring a two-stringed lyre, the two parallel lines corresponding to the strings having at times a slight golden tinge; the face presents three white spots forming between them a symmetrical triangle pointing downward; the proboscis is uniformly black, but when the white tips of the palps (in the female) are resting on the upper part of the sheath, they may be mistaken for markings on the proboscis. The shortness of the wings in the yellow-fever mosquito struck me as a very convenient differential feature; when closed they leave the last segment of the body uncovered; in the night mosquito (C. pungens or pipiens?) they are just long enough to cover the posterior end of the body; while in the other day mosquito referred to above, and which resembles the night mosquito in many respects, the wings when closed project beyond the posterior end of the body. The yellow-fever mosquito has a peculiar way of laying its ova, not in the shape of a neat boatlet, like the night mosquito, nor in an irregular lump like the other day mosquito, but singly, in rows, or irregularly disposed upon the surface of the water or upon the walls of the receptacle above the water-line.

With the yellow-fever mosquito, as with the generality of gnats, it is only the female that bites and sucks blood. It disappears from view when the temperature falls below 70° F., hiding, in a state of semi-hibernation, in dark corners, behind presses or book-shelves, etc., but comes out again, anxious to bite, when the temperature rises to between 70° F. and 80° F. The shortest interval between two successive bites, when the insect has had a full meal of blood, is forty-eight hours in the hot season, but when the temperature is cool the interval may extend to five or six days. Ovulation is to a great extent regulated by the opportunities which the insect has had of biting and sucking blood. As a rule, it does not bite before having been fecundated; one fecundation proves, however, sufficient for all the ova that are to be laid by a female. All the ova are not laid in one batch, but at different intervals, a new feed of blood being apparently necessary for every new batch. The natural longevity of the female insect varies considerably under different circumstances, and even when several are caged together some may be short-lived, while others attain an old age. Probably the circumstance of not being allowed to bite, so that all their ova cannot be laid, may tend to prolong the term of their lives. In the condition of semi-hibernation which is produced by a temperature of 40° to 50° F., Dr. Guiteras informs me that he has had under observation Stegomyia mosquitoes which have reached the age of two and a half months, without any food and with no other water supply but the droplets condensed upon the walls of the cage. A contaminated mosquito which had never been allowed to bite after its contamination lived at room temperatures upon sugar and with a provision of water, five months (from August to December, 1902). In their natural condition, however, even without taking into consideration their numerous exposures to violent death, I imagine that the yellow-fever mosquito seldom lives beyond forty or fifty days in the summer season. They have, moreover, many natural enemies, some of which attack them in the larval stage, as do the larvæ of the Psorophora, and others also as a winged insect. The yellow-fever mosquito is killed by temperatures above 40° C.

For a more technical account of the Stegomyia fasciata the reader must be referred to Prof. H. B. Ward's article on *Mosquitoes in Relation to Human Pathology* in Volume V. of this HANDBOOK.

PROPAGATION OF YELLOW FEVER.

A recognition of the fact that yellow fever can be transmitted in nature only through the agency of the contaminated Stegomyia mosquito leads to the following conclusions:

When a case of undoubted yellow fever originates in a locality known to have been free from the disease during a certain length of time, including several months of summer temperatures, in a person who has not absented himself from the locality during the last ten or fifteen days previous to his illness, one of three events must be supposed to have happened.

1. If in the locality considered the Stegomyia mosquito does not exist, one or more mosquitoes of that species having had opportunities for biting yellow-fever patients must in some way have been introduced and had access to the first person attacked with the disease. The incrim-

inated insect must have become infected since at least ten or twelve days, but possibly as far back as several months, before biting the new case on hand, and the latter was probably bitten by the contaminated mosquito between three and nine days before he was taken sick.

2. If the yellow-fever mosquito is a normal dweller in the locality which we are considering, there is a possibility that an unrecognized yellow-fever patient, within the first days of his illness (perhaps a passenger in a railway train stopping a few moments in the city station, on a ferry, or in any other conveyance) may have been bitten incidentally by one of the local Stegomyia mosquitoes, so that after the lapse of a couple of weeks cases of yellow fever may begin to develop in the locality.

3. Contaminated mosquitoes may be introduced with an immature contamination, so that the first non-immunes who happen to be bitten by them will not take the disease while, a few days later, every non-immune who is bitten by the same insects will be likely to be attacked with yellow fever within the week following the bite.

Manner in which Contaminated Mosquitoes may be Conveyed from One Place to Another.—The most obvious modes of conveyance include the casual imprisonment of contaminated insects inside of trunks, boxes, parcels, etc., and it sometimes happens that a mosquito is entrapped under a hat at the moment when it is actually biting the wearer's head. Within certain variable limits of time, in accordance with what has been said regarding the longevity of the yellow-fever mosquito, the contaminated insect may be restored to liberty when the trunk or the box comes to be opened, or the first time the wearer of the hat uncovers his head; and thus the foundation for an epidemic may be laid. The mosquito, as a rule, does not fly away to any distance from the dwelling where it has established itself; but it may wander away the length of one or two blocks in pursuit of a victim or when driven from its quarters by obnoxious fumes such as are developed in disinfecting a house or a room, if the retreat of the infected insects has not been cut off. With its short wings the yellow-fever mosquito is incapable of supporting itself in the air when a strong wind is blowing. Under these circumstances, if carried away by the wind from the deck of a ship, or from the shore, it might strive to save itself from drowning by alighting upon some floating object, which, drifting with the current, would perhaps land the insect at a greater distance than it could have reached flying. Vessels trading with ports in the yellow-fever zone are apt to be boarded by the Stegomyia mosquito, and new broods of that species may be developed in the water tanks or barrels, or in accidental collections of stagnant fresh water in any part of the ship. Fruit vessels or those laden with sugar must be particularly attractive to these insects. Thus it is evident that without any actual imprisonment the Stegomyia may make its temporary or permanent home in vessels as well as in public conveyances, railway carriages, freight cars laden with fruit, etc., when the local conditions are favorable. In the presence of so many sources of danger it must, therefore, be recognized that our only chance of actually controlling the propagation of yellow fever lies in our ability to carry out the following precepts:

1. To protect yellow-fever patients from the bites of mosquitoes.
2. To prevent the escape of any of the mosquitoes that have bitten a yellow-fever patient before adequate measures can be taken for their destruction.
3. To prevent the access of non-immunes to localities in which contaminated mosquitoes may still be alive.

The fact that by satisfying these conditions the propagation of yellow fever can be absolutely controlled has been fully demonstrated by Major W. C. Gorgas while he was at the head of the Sanitary Department of Havana, and by our subsequent experience in the same city, showing that non-immunes run no risk of becoming infected by staying in the presence of imported cases of the disease, when both the patient and the non-immunes are effectually protected against the bites of the yellow-fever mosquito. *Charles J. Finlay.*

YELLOW FEVER: SYMPTOMATOLOGY AND TREATMENT. See The Appendix.

YELLOW SPRINGS.—Greene County, Ohio. Hotel.

Access.—Yellow Springs is a station on the Little Miami Railroad, seventy-four miles northeast of Cincinnati (Walton).

The springs are pleasantly situated on the banks of the Little Miami River. The surrounding country is undulating, and attractive drives lead in all directions. The springs yield about six hundred and sixty gallons of water per hour. An analysis by Messrs. Wayne and Locke resulted as follows: One United States gallon contains (solids): Calcium carbonate, gr. 19.57; calcium sulphate, gr. 1.35; sodium chloride, gr. 0.15; magnesium chloride, gr. 0.17; calcium chloride, gr. 1.54; iron oxide, gr. 0.39. Total, 23.17 grains.

The water possesses mild diuretic and tonic properties. *James K. Crook.*

YELLOW SULPHUR SPRINGS. — Montgomery County, Virginia.

Post-Office.—Yellow Sulphur Springs. Hotels and cottages.

Access.—Via Norfolk and Western Railroad to Christianburg depot, thence three and one-half miles by stage to springs.

This resort is located near the summit of the Alleghany Mountains, at an elevation of 2,000 feet above the sea. We find here the usual beautiful scenery and charming climate characteristic of the Alleghany resort. Four miles north of the springs is the village of Blacksburg, the location of the Virginia Agricultural and Mechanical College and the State Experimental Station. The Montgomery White Sulphur Springs are also within a distance of only four miles. The Alleghany Springs are fifteen miles, and the wonderful Mountain Lake and Bald Knob eighteen miles distant. A large new hotel, having sixty-four bed-chambers, a handsome ball-room, a large and well-ventilated dining-room, numerous bath-rooms, etc., are among the recent improvements. The lawn and pleasure grounds are shaded by magnificent forest trees, whose dense foliage makes a delightful and luxurious shelter in warm weather. The Yellow Sulphur Springs yield one hundred and eighty gallons of water per hour. This water, which has a temperature of 55° F., is transparent and very palatable. Baths of this water are always to be had at any desired temperature. The following analysis of the water is taken from the United States Dispensatory for 1880, p. 1832:

One United States gallon contains (solids): Calcium carbonate, gr. 8.64; magnesium carbonate, gr. 1.38; iron carbonate, gr. 0.62; free carbonic acid, gr. 4.68; calcium sulphate, gr. 63.30; magnesium sulphate gr. 21.09; aluminum sulphate, gr. 3.18; potassium sulphate, gr. 0.11; sodium sulphate, gr. 0.75; calcium phosphate, gr. 0.01; magnesium phosphate, gr. 0. 01; potassium chloride, gr. 0.09; sodium chloride, gr. 0.08; organic matter, gr. 3.73; and traces of iron protoxide. Total, 107.67 grains.

The title to the designation "sulphur" water is not made clear by this analysis, yet it shows a valuable combination of mineral ingredients. The water should possess antacid, diuretic, and laxative properties. It contains sufficient iron to give it a tonic influence and enough free carbonic acid to impart a pleasant sparkle and to endow it with a grateful sedative action on the stomach. The water has been found, on continued use, to brace up and give tone to the muscular system and to allay chronic and subacute inflammation of the gastro-intestinal mucous membrane, thus regulating the secretory function, tranquillizing the nervous system, and tending to promote sound and refreshing sleep. It is highly recommended in chronic disorders of the female generative organs, especially in amenorrhœa, in dysmenorrhœa of certain forms, and in leucorrhœa. It also acts as a valuable restorative in general debility and in convalescence from acute prostrating diseases. The baths are recommended for rheumatism and chronic squamous skin affections.

James K. Crook.

YELLOWSTONE NATIONAL PARK SPRINGS.—The great Yellowstone Park is undoubtedly destined to become prominent as a health resort. Within its limits are contained upward of two thousand springs, many of which have been found to be highly mineralized as well as thermal. We present the following table of reactions, etc., of thirty-four of these springs, geysers, and streams, which we have compiled from analyses made in 1883, 1884, and 1885 by Messrs. Frank Austin Gooch and James Edward Whitfield*:

Springs and Geysers of the Yellowstone National Park.

	Temperature °F.†	Reaction.	Solid contents per U. S. gallon.‡

† Converted from degrees centigrade.
‡ Converted from grams per kilograms.

Most of these waters, it will be seen, are not only highly thermal, but are quite heavily mineralized, the solid contents ranging from 12.24 to 197.05 grains per gallon. These mineral ingredients consist chiefly of calcium, sodium, potassium, lithium, magnesium, silicon dioxide, sulphur trioxide, carbon dioxide, chlorine, and basic oxygen. The chemists also discovered the following ingredients in small quantities or traces: Titanium, arsenic, iron, bromine, aluminum, manganese, barium, strontium, rubidium, cæsium, ammonium, hydrogen sulphide, boron, phosphoric and hydrochloric acids. The various combinations of these elements and bases have not been fully determined, but the waters may in general terms be classed as calcic, alkaline, silicious, saline, and sulphureted. It may be stated that the waters for the above examinations were collected during the months of July, August, September, and October, and the thermometric records represent as a rule the summer temperatures. It is probable that the waters of the hot springs show little variation in temperature at the fountains during the year. We present in full the analysis of the Fountain Geyser, which may be regarded as fairly representative of the group. The hypothetical combinations have been worked out for the author by E. E. Smith, M.D., Ph.D., of New York.

Fountain Geyser (Yellowstone National Park). One United States gallon contains (solids):* Sodium chloride, gr. 30.47; potassium chloride, gr. 2.09; sodium bromide, gr. 0.03; lithium bicarbonate, gr. 1.98; sodium bicarbonate, gr. 22.46; magnesium bicarbonate, gr. 0.35; calcium bicarbonate, gr. 0.33; iron bicarbonate, gr. 0.035; potassium sulphate, gr. 2.48; sodium phosphate, gr. 0.01; sodium tetraborate, gr. 1.16; sodium arseniate, gr. 0.20; alumina, gr. 0.96; silica, gr. 19.33; and a trace of manganese bicarbonate. Total, 81.885 grains. The water also contains free carbonic acid and a trace of sulphureted hydrogen.

This analysis presents a fairly strong alkaline-saline water. It possesses useful properties as an antacid, diuretic, and aperient. In addition, it contains an appreciable quantity of arsenic, and in continued dosage should speedily produce the physiological effects of that drug. The water of La Bourboule, in France, which contains but slightly more arsenic than this geyser, has long been celebrated in the treatment of skin diseases, notably in eczema and the other rheumides. The Yellowstone waters will no doubt in time be found to possess equal virtue in these affections. At the present time the waters are used for bathing only at the Fountain Geyser Hotel. At this resort the waters are conducted into the hotel building, which is supplied with an excellent system of bath-rooms. The thermal waters of the park will probably come into high repute, in the near future, in the treatment of gout, rheumatism, and syphilitic affections. Some of the springs contain a considerable proportion of sulphureted hydrogen, while free hydrochloric acid is found in several others. We may expect that all of these different waters will at some future time render useful service in practical therapeutics. We are informed that intensely hot weather is practically unknown in the park. Following is a temperature table of the summer and early autumn months, made during a recent season:

	Sunrise.	Midday.	Sunset.	Mean.
July	55° F.	77° F.	69° F.	67° F.
August	50	79	66	65
September	41	66	58	55
October	41	57	52	50

Visitors to the park should be amply prepared for cool weather, no matter what the season may be.

James K. Crook.

YERBA SANTA.—(*Eriodictyon*, U. S. P.; "Consumptive's weed," "Mountain balm," etc.) The dried leaves of *Eriodictyon Californicum* (H. et A.) Greene (fam. *Hydrophyllaceæ*). A very pretty evergreen shrub, growing on the western side of the United States and in northern Mexico, in gregarious clumps and patches in barren soils and among rocks. The drug is thus described: Usually much broken; blade narrowed into a very short and broad petiole, 5–12 cm. (2–5 in.) long and rarely exceeding 3 cm. (1¼ in.) in breadth, oblong-lanceolate, gradually tapering to an acutish point, most irregularly serrate- or crenate-dentate, thick and brittle, or flexible in a damp and warm atmosphere, the margins more or less incurved; upper surface yellowish-green, more or less resinous, smooth, the veins somewhat impressed; lower surface whitish or yellowish-white, with finely and conspicuously reticulate dark veins, densely but very shortly tomentose; odor somewhat aromatic, strongly balsamic if heated in the closed hand; taste balsamic, sweetish, somewhat tea-like.

The principal constituent of this drug is its ten to twelve per cent. of resin, divisible into two parts, one of which, constituting its chief bulk, possesses the property of precipitating quinine from its salts. It also contains volatile oil, ericinol, sugar, and the peculiar body *eriodictyonic acid*, which in some respects resembles tannin.

---

* Bulletin 47 of the United States Geological Survey, 1888.

* The combinations, as estimated by the original analysts, have recently come under our observation. The result does not materially differ from those given above. It is probable that the proportion of sodium arseniate is somewhat over-estimated.

Yerba santa, as one of its names shows, has a local reputation on the Pacific slope for coughs, colds, bronchitis, and phthisis, a reputation which is shared by many other resinous substances and has some foundation. It is also a pretty good vehicle for the administration of quinine, whose taste, like liquorice or glycyrrhizin, it covers pretty well. Of the official fluid extract, 3 or 4 c.c. (♏ xlv. ad lxv.) may be given for coughs. A syrup, as a vehicle for quinine, is sometimes prepared.

Henry H. Rusby.

YOLK SAC.—(Umbilical vesicle: Vitelline sac.) Since the human yolk sac is a vestigial organ, its significance can be appreciated only after examining the corresponding structure in other animals.

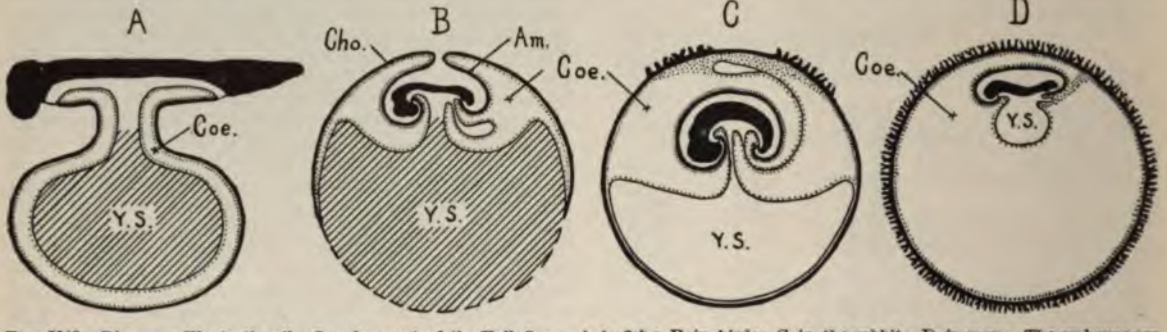

FIG. 5046.—Diagrams Illustrating the Development of the Yolk Sac: *A*, in fish; *B*, in birds; *C*, in the rabbit: *D*, in man. The embryos are drawn in black, the ectoderm in heavy lines, the entoderm in light lines, and the mesoderm in dotted lines. The yolk is shaded. *Am.*, Amnion; *Cho.*, chorion; *Coe.*, extra-embryonic cœlom; *Y. S.*, yolk sac. (After Hertwig, Duval, and Minot.)

COMPARATIVE EMBRYOLOGY.—In fish embryos the entoderm lining the digestive tract is distended ventrally, and its cells are loaded with nutritive material in the form of granules. This solid mass of yolk-laden entoderm is covered on the outside with a layer of mesoderm, and the entire structure is known as the yolk sac. In sharks the sac joins the body by a constricted portion, the yolk stalk (Fig. 5046, *A*). The ventral body wall, composed of ectoderm with a lining of mesoderm, extends over the yolk sac, but is separated from it by an extension of the body cavity or cœlom. As the fish grows, the yolk is consumed as food and the ventral swelling is gradually taken up until no trace of it remains. In the mesoderm of the yolk sac blood-vessels develop very early and extend to and from the body of the embryo. In some viviparous sharks the vascular yolk sac is thrown into folds which, by fitting into corresponding uterine folds, also vascular, constitute a sort of placenta (Balfour).

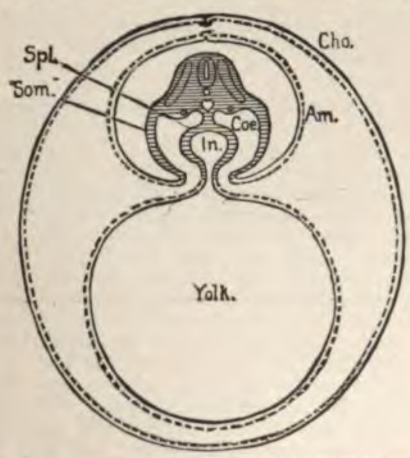

FIG. 5047.—Diagrammatic Cross-Section of an Amniote Embryo. The body of the embryo is shaded; the extra-embryonic mesoderm is represented by a dotted line. *Som*, somatopleure; *Spl*, splanchnopleure; *Cho*, chorion; *Am*, amnion; *Coe*, cœlom; *In*, intestine; *Yolk*, yolk sac. (Minot.)

In birds the yolk material is enormously developed, and, though not at first divided into cells, is still to be regarded as intracellular and as belonging chiefly to the entoderm. The germ layers spread gradually over its surface (Fig. 5046, *B*). The small embryo sinks into the yolk mass, and the ectodermal layer, with the accompanying mesoderm, closes in over its back to form the amnion, *Am*, and to become cut off from the chorion, *Cho*. The extra-embryonic cœlom consequently becomes dilated. These relations are further illustrated in the cross section, Fig. 5047. From the posterior end of the intestinal tract an out-pocketing projects into the cœlom, in which it lies free. This entodermal pocket is the allantois, an organ composed of the same layers as the yolk sac, and like it, highly vascular. Its competition with the yolk sac in placental mammals will be described presently. The yolk sac of birds, in later stages, is drawn into the abdominal cavity, and there it remains in water fowl, as a permanent diverticulum at about the middle of the small intestine. (Oppel.)

The mammals present several types of yolk sac. Except in the monotremes the sacs are empty; the yolk-charged protoplasm has given place to a single layer of well-defined entodermal cells surrounding a cavity filled with thin fluid. The conditions in the rabbit, at a stage comparable with the bird, *B*, are shown in Fig. 5046, *C*. The allantois does not lie free in the cœlom, but has fused with the chorion, into which its vessels extend to form the fœtal part of the placenta. In the rabbit the cœlom never extends farther around the yolk sac than is shown in the figure. The lower half of the sac consists of entoderm and ectoderm only. This lower half soon breaks down and disappears, leaving the entoderm of the upper half to rest against the uterine wall. It is then said to become villous and perform placental functions. (O. Schultze.) Except in some rodents and in the marsupials, the mesoderm extends completely around the yolk sac. In the marsupials the sac is large, almost enveloping the embryo and its amnion. It unites with the chorion and becomes the fœtal portion of the placenta. (Osborn.) The allantois in these animals does not reach the chorion. In the carnivora both yolk sac and allantois are connected with the chorion until birth, and both are vascular. The horse shows similar relations, but the area of chorionic connection with the yolk sac becomes very small, and at birth is merely a scar. (Bonnet.) In ruminants and swine the contact of sac and chorion is slight and transient. In Tarsius and the primates the yolk sac is very small, and in early stages quite distant from the chorion (Fig. 5046, *D*). The extra embryonic cœlom is correspondingly greatly developed. The human yolk sac is therefore a small and rudimentary organ, neither containing yolk material nor performing placental functions.

Gross Anatomy of the Human Yolk Sac.—The youngest human embryos known, and those 1.5 mm. long, are attached to a rounded yolk sac having a diameter equal to the length of the embryo and being connected with nearly the whole extent of the intestinal tract. The embryo grows faster than the yolk sac. At 2.15 mm. the relations are those shown in Fig. 4827 in the present volume. The opening of the globular yolk sac now occupies the middle third of the entodermal tract. A little later the sac becomes pyriform (Fig. 4829), and its intestinal orifice is relatively much smaller. In embryos of about 7 mm., or in the fourth week, the yolk sac is said to attain its maximum development. It is then round or oval, 4–7 mm. in diameter, connected with the intestine by a slender yolk stalk. The sac lies between the amnion and the chorion; its stalk has become included in the umbilical cord (see *Umbilical Cord*, and Fig. 4831). Subsequently the yolk stalk loses its lumen and proceeds to disintegrate, beginning at a point near the future umbilicus. Thus in a three months' embryo the yolk stalk is found in the proximal part of the cord, but no trace of it exists in the distal portion. At birth the part within the cord has gone, but beyond the cord, between the chorion and amnion, traces of it are found, and the sac itself is almost invariably present. (? Mayer, 1834; B. S. Schultze, 1861.)

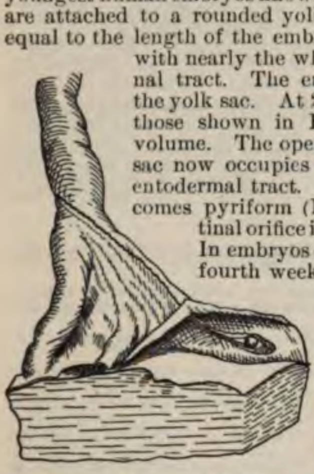

Fig. 5048.—The Placental Insertion of an Umbilical Cord, showing Schultze's Fold. A part of the amnion covering the fold has been reflected, disclosing the yolk sac and persistent vitelline vessels. One-half natural size. (After Lönnberg.)

The umbilical cord is attached to the mature placenta at an angle varying from 0° to 90°. If the cord is gently extended, a thin, triangular or crescentic fold may be expected in this acute angle of insertion. It is thinner than other folds, which are due to blood-vessels. Sometimes it is inconspicuous or absent; in other cases it is 5 or 6 cm. high and very prominent as in Fig. 5048. It is the only place where the amnion is not closely adherent to the cord. In it and beyond it Wharton's jelly is found, sometimes extending a considerable distance over the placental surface. The amniotic villi occur chiefly on this fold. (Winkler, 1868.) According to its discoverer, Schultze, the fold is caused by the yolk stalk, which, if present, is seen within it as a delicate thread running just beneath the surface. It may be absent, or present in detached fragments, occasionally it is continuous from the cord to the yolk sac. If the amnion is removed from the chorion in the quadrant indicated by Schultze's fold, the *sac* will appear as a round or oval vesicle adhering to the amnion (rarely to the chorion), being about 5 mm. in diameter, and possessing a whitish, yellow, brown, or greenish nucleus. Lönnberg, in two hundred placentas, found the yolk sac under the placental area thirty-one times, at the placental border nine times, and beyond the placenta one hundred and sixty times, an extreme case being 27 cm. from the placental insertion of the cord.

The proximal end of the yolk stalk enters the ileum. In young embryos the extensive loop of intestine to which the stalk is attached is found outside of the body, in the cœlom of the umbilical cord. As the intestine is withdrawn into the body, a part of the yolk stalk passes from the navel inward, to a point on the small intestine which at birth is about one foot from the cæcum, and in the adult some four feet. This section of the yolk stalk is normally obliterated. The place where it entered the intestine may be marked by a diverticulum, generally less than four inches in length, although sometimes much longer, known as Meckel's diverticulum. Meckel in 1809 understood its origin and knew that the yolk sac was never connected with the vermiform appendix!

Blood-vessels. — The vitelline, omphalo-mesenteric, or omphalo-mesaraic vessels, which supply the yolk sac, are among the first blood-vessels to develop. In young chick embryos blood from the yolk sac enters the body by two veins which unite to form the heart. These are the vitelline veins. From the heart two arteries extend back along the body of the embryo and branch out on either side over the yolk sac. There a vascular network places them in connection with the veins just described. In later stages a caudad continuation of each artery in the body of the chick causes the portion which passes to the yolk sac to appear as a branch, the vitelline artery. The stems from which these branches arise fuse to form the dorsal aorta. In mammals there are at first many vitelline arteries on each side, irregularly distributed. These are replaced by a few vessels said to be segmentally arranged in pairs. (Mall, Tandler.) Finally a single pair becomes predominant.

By the early development of the vitelline circulation the nutritive yolk is transferred to the body. The spread of the vascular network over the yolk proceeds from the embryonic pole. Its extent is bounded by an encircling vessel, the terminal sinus. This sinus is well defined in birds, is less distinct in mammals, and in man has never been seen, since in the youngest known human embryos the yolk sac is already completely covered with blood-vessels. In birds the vitelline area is the seat of the extensive formation of blood corpuscles, and in mammals it may have the same function.

The vitelline arteries fuse with one another between the aorta and the intestine, and again ventral to the intestine. The intestine becomes encircled by a vascular ring, one half of which, usually the left, soon disappears. A single vitelline artery is thus formed which passes on the right side of the intestine to the yolk sac. With the degeneration of the yolk sac this artery is obliterated, except that portion between the aorta and intestine, which remains as the superior mesenteric artery.

The vitelline veins, at first a pair, also fuse, and form two loops around the intestine. From the intestine they extend as a single fused vessel across the abdominal cavity to the umbilicus. The distal part of this vein is later obliterated. Portions of the loops around the intestine become the portal vein, from which a new branch arises to form the superior mesenteric vein (Dexter).

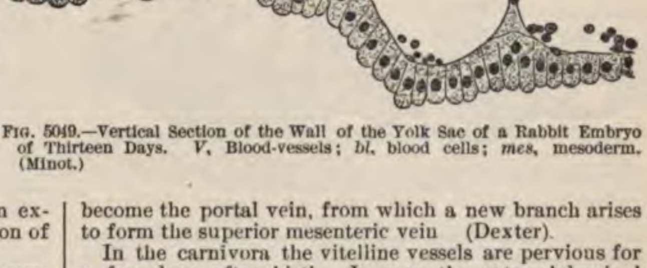

Fig. 5049.—Vertical Section of the Wall of the Yolk Sac of a Rabbit Embryo of Thirteen Days. *V*, Blood-vessels; *bl*, blood cells; *mes*, mesoderm. (Minot.)

In the carnivora the vitelline vessels are pervious for a few days after birth. In man the extra-abdominal part is usually obliterated in the first half of pregnancy. Cases of persistent vitelline vessels at birth have been reported, first by Bischoff in 1834. Lönnberg states that there may be two, three, or four vessels, usually three. The arteries may anastomose with the umbilical arteries, but the vein goes through the cord to enter the fœtus directly. Fig. 5048 shows the persistent vessels around the yolk sac.

HISTOLOGY.—The wall of the yolk sac of a young rabbit consists of two layers, a lining of simple cylindrical entodermal epithelium and an outer layer of vascular mesoderm (Fig. 5049, from Minot). The latter soon appears divisible into mesenchyma and mesothelium. These with the entoderm make the three layers which are characteristic of later stages. The lining of the human yolk sac is said to be of simple epithelium at first. Subsequently it becomes stratified and thrown into folds, variously interpreted. Kölliker and von Baer have described villi containing blood-vessels, and Paladino has figured irregular elevations in the yolk sacs of dog and rabbit. Tourneux found epithelial depressions extending into the mesoderm, separated from one another by mesodermal papillæ. Spee observed slender tubes of entoderm extending across the mesoderm, branching dichotomously, and ending in alveolar enlargements. These he found all over human yolk sacs of six to nine weeks. With Paladino, who regards the mammalian yolk sac as a gland with an internal secretion, and Saxer who finds it a blood-forming organ containing giant cells and blasts, Spee unites in making comparisons with the liver.

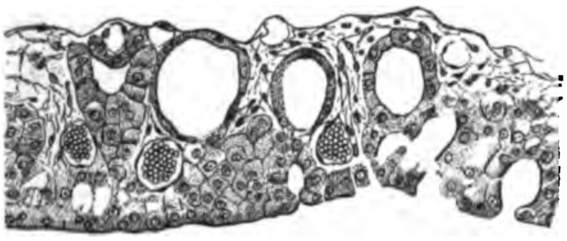

FIG. 5050.—Cross Section of a Human Yolk Sac, from a 9.4 mm. Embryo. × 95 diameters.

The yolk sac of a human embryo 9.4 mm. long, of about four weeks, is without villi. Its proliferated epithelium shows alveolar pockets sometimes resting on the mesothelium and often having no outlets. Between the alveoli there is a small amount of vascular mesoderm, covered with a layer of mesothelium (Fig. 5050).

In a better preserved yolk sac from a 23 mm. embryo of about two months, only an occasional epithelial cyst is found. The dense mesenchyma forms a more definite layer, and the mesothelium is quite distinct (Fig. 5051). The blood-vessels cause elevations on the outer surface which are macroscopic. The entodermal cells are vacuolated, probably containing fat droplets, and are degenerating. They possibly account for some of the stages in blood formation described by Saxer. The resemblance with the liver seems to be remote. At birth the entoderm has wholly disappeared, leaving a connective-tissue envelope surrounding débris, calcareous granules, fat, and albuminoid bodies (Lönnberg). Rauber described yolk elements lying free in the mammalian yolk sac. If yolk is present it should be within the entodermal cells; probably Rauber's yolk is a degeneration product.

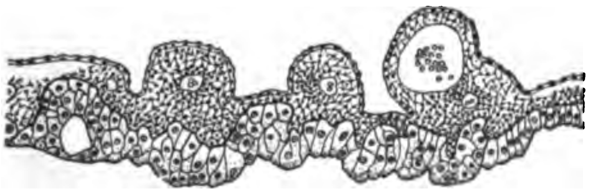

FIG. 5051.—Cross Section of a Human Yolk Sac from a 23 mm. Embryo. × 95 diameters.

The yolk stalk in the cord can be distinguished from the allantois by its cylindrical epithelium, generally simple, but sometimes two- or three-layered. The epithelium of the allantoic duct is cuboidal.

PATHOLOGY.—Meckel's diverticulum may contain concretions, and become inflamed like the vermiform appendix. The intra-abdominal yolk stalk sometimes persists as a band of fibrous tissue, a frequent cause of intestinal obstruction. (Fitz.) Portions of the stalk may form large cysts, and be connected with the intestine or the umbilicus, or lie free in the mesentery. (Roth.) The stalk may remain open from intestine to umbilicus, producing an intestinal fistula. (Neurath and Roth.) Fungiform adenoma at the umbilicus has been attributed to the yolk stalk remains. (Hüttenbrenner.) Cysts which may be numerous along the extra-abdominal yolk stalk (Ahlfeld) and persistent vitelline vessels have no harmful effect upon the fœtus.

Frederic Thomas Lewis.

YOUNG'S NATURAL GAS WELL AND MINERAL SPRINGS.

—Lake County, California.

These natural wonders are located in the eastern edge of Kelseyville on a slightly elevated ground, about three miles south of Clear Lake and near the base of Uncle Sam Mountain. The well is, so far, more of a curiosity than a health resort. While boring for gas, in 1888, the proprietors set free, at a depth of about one hundred and fifty-eight feet, a large volume of water mingled with gas. It rushed out with great force, and the flow has continued, geyser fashion, ever since. For an instant it stops, and then comes another violent ejection to the height of about forty feet; this occurs as often as seventy or eighty times to the minute. The flow of water, which has a temperature of 76° F., is about six thousand gallons per hour. Many people from various localities visit the place to witness the peculiar phenomenon. The water has been extensively used by the people of Kelseyville and vicinity, and they pronounce it excellent for liver, kidney, and bowel disorders. The following analysis of the water was made by Winslow Anderson in 1889. One United States gallon contains (solids): Sodium chloride, gr. 15.76; sodium carbonate, gr. 36.52; sodium sulphate, gr. 19.16; potassium carbonate, gr. 3.40; potassium iodide, gr. 0.78; magnesium carbonate, gr. 7.14; magnesium sulphate, gr. 21.90; calcium carbonate, gr. 6.36; calcium sulphate, gr. 0.72; manganese carbonate, gr. 0.18; ferrous carbonate, gr. 4.95; borates, gr. 3.12; alumina, gr. 5.18; silicates, gr. 6.45; and traces of barium carbonate, lithium carbonate, and organic matter. Total solids, 140.62 grains. Free carbonic acid gas, 9.60 cubic inches; also traces of petroleum and carbureted hydrogen (inflammable gas).

The water may be described as a fairly strong saline chalybeate. If sufficiently palatable it ought to prove useful as a therapeutic agent. Its action is tonic, antacid, aperient, and diuretic. It is the owner's intention to establish a health and pleasure resort on the premises. Several inflammable gas wells are also found on the ground. These yield a gas composed largely of light carbureted hydrogen. *James K. Crook.*

YUMA, ARIZONA.—This desert "city" of 1,800 inhabitants lies in the extreme southwestern corner of Arizona, at the junction of the Gila and Colorado rivers. It has an elevation of only 140 feet, and is situated in the Great Arizona Desert, about sixty miles from the Gulf of California and a few miles from the Mexican border. It is on the line of the Southern Pacific Railroad.

Like Phœnix in the same State, Yuma is famed for its sunshine, heat, and dryness. It can be used only as a winter resort, for it is excessively hot in the summer, the thermometer sometimes rising as high as 115° F. or over, and for many days in succession it ranges above 90° F.

Such a region and climate present conditions closely resembling those which are found at the health resorts of Egypt, which are in nearly the same latitude. The accommodations in the latter country, however, are vastly superior in abundance and excellence to those at Yuma, which are insignificant in comparison, although we are told that "ample accommodation is had at the Depot Eating House, situated on the very bank of the Colorado, with encircling balconies for enjoyment of guests." One would hardly choose, however, a railroad station for a pulmonary invalid seeking pure air free from dust. What other suitable accommodations, if any, exist is unknown to the writer. There is little at Yuma to attract one in the way of amusements or diversion. Such vegetation as is found here is of a semitropical nature. The soil is that which is peculiar to all desert regions.

The climate is that typical of the desert in a tropical latitude, and presents many interesting phases for study. In the first place, we observe from the chart that there are 282.4 clear days, and 351.7 clear and fair days, or over 90 per cent. The mean number of cloudy days for 6 years was 21 (Solly). One may therefore enjoy here almost continuous sunshine. What a contrast, for instance, to Sitka, Alaska, where there are only 66 clear days on an average during the year! Secondly, the extraordinary heat of the warmer months of the year is to be noticed, the temperature in the shade having been known to rise as high as 118° F.; and in the year 1893, from April to October inclusive, out of 214 days, there were 162 during which the thermometer stood above 90° F., and the maximum temperature for the year was 117° F. (Solly, "Medical Climatology.")

It is to be borne in mind, however, that this is a very dry heat—the dryness of the desert, and hence more endurable than a lower temperature would be in combination with a moist atmosphere. From the table we see, again, that the relative humidity is very low, 40.3 per cent. for the year; and the average rainfall for the year only 2.08 inches, and in some years much less than his. Thus, for example, in 1899, there was only 0.6 inch of rain, 0.5 of which fell in November. (Hinsdale, "System of Physiologic Therapeutics, Climatology.") The winter climate, the season in which an invalid would seek such a resort, is sunny and mild, the average temperature being 56.1° F., about five degrees higher than that at Phœnix for the same season, and about two degrees lower than that of Cairo, which is 58.3° F.

CLIMATE OF YUMA, ARIZONA. LATITUDE, 32° 45′; LONGITUDE, 114° 36′.—PERIOD OF OBSERVATION, EIGHT YEARS.

For a comparison of the climate of this desert region of Arizona with that of the winter resorts of Egypt, the reader is referred to the article on the latter country in Vol. III. of this HANDBOOK. It will be seen how closely the climatic characteristics of these two regions resemble each other; both illustrate the features of a warm desert climate, and with equally good accommodations and attractions both would probably produce similar results in the treatment of disease.

The conditions and diseases for which such a climate as that to be found at Yuma is to be recommended are also those for which the Egyptian climate is favorable. All stages of phthisis may be favorably influenced by a residence in this desert climate, provided the conditions are not acute. As in Egypt, the disadvantage of such a resort is the short time of year during which it is available; this is a distinct objection in the treatment of phthisis, although even with this disease change is sometimes desirable and advantageous, and this is oftener true of many other maladies. Change *per se* is a therapeutic resource of no mean value.

For the consideration of the climate of Arizona as a whole, the reader is referred to the article on *Arizona* in Vol. I. of this HANDBOOK. *Edward O. Otis.*

ZEDOARY.—(*Rhizoma Zedoariæ*, P. G.) The rhizome of *Curcuma Zedoaria* Roscoe, order *Zingiberaceæ*. This is one of the numerous ginger-like plants which inhabit the warmer parts of Asia, and whose rhizomes or seeds are used as spices or condiments. Zedoary is indigenous in India and China, in which places it is also cultivated. It is introduced and cultivated also in Java and other Pacific islands. The rhizome is the part used, being dug up, washed, or scraped, and then sliced and dried. It is commonly stated that the smaller branches form the "long Zedoary," and the central tubercles or clumps the "round Zedoary"; but, according to the French Codex and some other authorities, the latter is the rhizome of a related plant, *C. aromatica* Salisbury. Zedoary comes also occasionally mixed with curcuma. The long variety of Zedoary is of old occurrence in commerce, and was formerly a greater favorite than now, when its place is mostly taken by ginger, curcuma, sweet flag, etc. In this country, indeed, it is wellnigh obsolete, but on the continent of Europe it is still official in most countries, although but very little used.

It figures mostly in external applications as an ingredient of several proprietary liniments and "balsams." The French "*Baume de Fioravanti*" contains zedoary along with fifteen other resins and spices.

In its composition zedoary resembles ginger and curcuma, and like these it contains an abundance of starch.

W. P. Bolles.

ZEM ZEM SPRINGS.—Lake County, California.

These springs are located on the southeastern side of Clear Lake, and take their name from the Holy Well in Mecca. The waters have a temperature of 64° F., and, according to an analysis said to have been made by Dr. Boon, they contain the following ingredients: One United States gallon contains: Sulphur, gr. 291.15; iron, gr. 157.50; magnesia, gr. 163.24; solid matter, gr. 612.15. Total solids, 1,224.04 grains.

They have some notoriety in the treatment of dyspepsia, rheumatism, and diseases of the liver and kidneys.

ZENKER'S NECROSIS. See *Muscle, Pathology of*, and *Necrosis*.

ZINC.—I. GENERAL MEDICINAL PROPERTIES OF COMPOUNDS OF ZINC.—Charging the blood with zinc affects nutrition in excess, developing poisonous symptoms, but the action is not so profound as with the majority of the heavy metals, and in medicinal dosage deleterious effects need not be feared. Therapeutically, the constitutional influence shows itself in a tendency—not very strongly pronounced, but still useful—to abate spasmodic nervous disorders, such as epilepsy, chorea, hysteria, etc. Indeed, before the rise of bromides into medicinal prominence, zinc was a standard medicine for the relief of epilepsy and hysteria. At present, it can only be said that, among the heavy metals, zinc combines more potency and availability as a constitutional nervine than any other—which is not saying much. Locally, the properties of the zinc compounds differ with the chemistry of the different compounds, mainly according to solubility, the soluble salts being caustic or irritant and astringent, and the insoluble compounds operating as absorbent, soothing, healing, and disinfectant dressings. Internally, the soluble compounds in moderate dosage determine prompt and thorough vomiting, after the manner of copper salts, though with less severity of action. In large doses they are corrosive or irritant poisons, according to the activity of the individual compound. The insoluble compounds in small dose allay gastric and intestinal irritability, but in large dose, probably through chemical conversion, may nauseate, and even vomit. Zinc compounds are disinfectant, the soluble salts, especially the chloride, notably so, and since they do not stain they are the most generally available of metallic salts for the purpose.

The *therapeutics* of zinc consist of the following applications: *constitutionally*, as a medicine of second- or third-rate power to control spasmodic nervous disease; *in the stomach*, to allay pain or nausea, for which purpose an insoluble compound is commonly selected; *in the bowels*, to control diarrhœa, especially when the affection seems a reflex of nervous irritation rather than the expression of a catarrh; and, *externally*, the soluble compounds, to cauterize, or, to perform the usual functions of a metallic astringent irritant in the way of determining absorption of granulation tissue, and abating catarrh; and the insoluble preparations to act as soothing, healing, or, applied dry, absorbent and disinfectant dressings. Solutions of the soluble salts are also available as efficient disinfectants of their kind for wounds, fabrics, floors, and all non-metallic receptacles.

II. THE COMPOUNDS OF ZINC USED IN MEDICINE.—These are the *oxide, carbonate, chloride, bromide, iodide, sulphate, acetate, valerianate*, and *phosphide*, and although not official, the *nitrate* and *oleate*.

Zinc Oxide (ZnO).—Zinc oxide is official in the United States Pharmacopœia as *Zinci Oxidum*, Zinc Oxide. It is a smooth white powder, odorless and tasteless, and insoluble in either water or alcohol. It dissolves in acids without effervescence. It is permanent in the air, but should be kept in well-stoppered bottles. Zinc oxide is a commercial article, and impure and even fraudulent specimens are not uncommon. Zinc oxide is the principal insoluble zinc compound. It may be used, given internally, for the constitutional effect of zinc, or to allay vomiting or diarrhœa; dose, from 0.06 to 0.30 gm. (gr. i.–v.), several times a day, in powder or pill. Externally, zinc oxide may be used, alone or mixed with powdered starches or gums, as an absorbent powder dressing to excoriations and sores, or, in ointment, as a soothing and healing application, for which purpose it is very efficient. There is an official ointment, *Unguentum Zinci Oxidi*, Ointment of Zinc Oxide, consisting of twenty per cent. of the oxide in benzoinated lard, which may be applied in full strength to sores or eruptions.

Zinc Carbonate.—Normal zinc carbonate occurs in the mineral *zinc spar* or *calamine*, which was formerly official in the United States Pharmacopœia, as a medicine, but was dropped, because of its impurities, in the revision of the Pharmacopœia of 1860. In its place is official, now, the mixture of carbonates that results from precipitating a boiling solution of zinc sulphate by sodium carbonate. Such precipitate is entitled *Zinci Carbonas Præcipitatus*, Precipitated Zinc Carbonate. Precipitated zinc carbonate is, like the oxide, a smooth, white powder, without odor or taste, and insoluble in water or alcohol. It dissolves in acids with copious effervescence. Zinc carbonate is substantially a duplicate of the oxide in medicinal properties, but its use is commonly confined to external application as an absorbent powder.

Zinc Chloride ($ZnCl_2$).—The salt, commonly called *butter of zinc*, is official in the United States Pharmacopœia as *Zinci Chloridum*, Zinc Chloride. It occurs in a white crystalline powder, or in white, opaque lumps, and is exceedingly deliquescent. It is odorless, but has a very caustic saline and metallic taste (but it is so corrosive that tasting is dangerous). It dissolves very freely in water and in alcohol. It should be kept in small, glass-stoppered bottles. The chloride is the most active of the zinc salts, being highly corrosive and antiseptic both. It has little effect on the sound skin, but upon a raw surface or mucous membrane it disorganizes tissues, forming a white, tough slough. The action, though powerful, is not diffuse, so that it can be regulated quit exactly in area and depth. The slough remains odorles during its attachment, and, when finally cast off, as happens in a week or ten days, exposes an underlying surface presenting clear, healthy granulations, which rapidly proceed to cicatrization. Zinc chloride thus make an excellent escharotic, combining the features of bein powerful, yet manageable, of disinfecting its own sloug for determining kindly healing of the resulting ulcer, an of being free from danger of producing constitution poisoning. Its operation is, however, very painful. I solution, zinc chloride is a standard disinfectant, but, strong, acts upon metallic surfaces. Internally, it is corrosive or irritant poison, according to concentration.

For use as a caustic, patent lint may be soaked in concentrated solution of the salt, dried, and then cut with an old, worthless pair of scissors—into proper siz and applied to the part, which, if covered with skir must first have the epithelium removed by blisterin Much more convenient, however, is the plan of makin the chloride into a paste with flour and water. Suc paste can be applied moist, or may be dried and cut int pointed rods, which are then available for thrusting int any large mass requiring destruction, such as a cancerou tumor. This paste was devised by a Dr. Canquoin, o Paris, and often goes by his name. It is made by rapi admixture of zinc chloride and wheat flour with a very little water—a few drops only to the ounce of paste. The strength in zinc salt will range from fifteen to thirty per cent., according to the character of the tissue requiring destruction.

As a disinfectant, zinc chloride can be prescribed in the official *Liquor Zinci Chloridi*, Solution of Zinc Chloride. This is a solution of the salt in water, fifty per cent., by weight, in strength. It is made directly from the metal by the action of hydrochloric acid, the resulting solution being purified from contaminating iron by a special procedure, and brought to standard strength by distilled water. The solution is a clear, colorless liquid, odorless, having a very astringent, sweetish taste and an acid reaction. In its pharmacopœial strength, this solution is entirely too strong for direct application, being, indeed, corrosive. As a general disinfectant, it should be diluted to three-per-cent. strength, and as a lotion for wound surfaces or ulcers to one per cent. It has the merit of being deodorant and disinfectant, while at the same time it has no smell, does not stain, and, in the dilution enjoined, does not attack fabrics nor injure metallic receptacles.

Zinc Bromide ($ZnBr_2$).—Zinc bromide is official in the United States Pharmacopœia as *Zinci Bromidum*, Zinc Bromide. It is a white, or nearly white, granular powder, very deliquescent, odorless, having a sharp saline and metallic taste, and a neutral reaction. It is very soluble in water and in alcohol. Because of its ready deliquescence, the salt should be kept in small glass-stoppered bottles. Zinc bromide closely resembles the chloride in general properties, being deliquescent and highly irritant. Its official recognition is, however, not for its duplicature of the chloride in uses, but for its internal employment in nervous disease, with the notion of getting the combined antispasmodic effect of zinc and a bromide. But in the small dosage which the character of salt enjoins, the quantity of bromine ingested is medicinally insignificant. The salt is given in doses of from 0.10 to 0.30 gm. (gr. iss. to v.) in syrupy solution.

Zinc Iodide (ZnI_2).—Zinc iodide is official in the United States Pharmacopœia as *Zinci Iodidum*, Zinc Iodide. This is, again, a white, granular and very deliquescent powder, odorless, but of a sharp, saline, and metallic aste. It is very soluble in water and in alcohol. It must be kept in small glass-stoppered bottles. Zinc odide, like the bromide, resembles the chloride in quality; but, like the bromide, is suggested for the purpose f getting the effects of the acid radical along with those zinc, in constitutional medication. But, again, the cessarily small dosage defeats the purpose. The salt given in doses of from 0.10 to 0.30 gm. (gr. iss. to v.) syrup. Locally, the iodide has been applied for the neral purposes of the metallic astringents, in solutions nging in strength from the one-fifth of one per cent. to per cent., or in a twelve-per-cent. ointment.

Zinc Sulphate ($ZnSO_4.7H_2O$).—Zinc sulphate is official the United States Pharmacopœia as *Zinci Sulphas*, Sulphate. It is crystalline, occurring in small, orless, right rhombic prisms, or acicular needles ich slowly effloresce in dry air. It is odorless, but has harply saline, metallic, and nauseous taste. It dis es in 0.6 part of cold water and in 0.2 part of boil water. It is insoluble in alcohol. It should be kept well stoppered bottles. Zinc sulphate is the sulphate se commercial impure variety is called *white vitriol*. pure quality, official as above, is in the small crys described, which look not unlike those of Epsom

Zinc sulphate is decomposed by alkalies and their onates, hydrosulphates, lime water, soluble lead salts, vegetable astringents. By heating, it can be made art with its water of crystallization, forming what lled *dried zinc sulphate*.

sulphate is an irritant astringent, and, in the dried is even caustic, though less powerfully so than the ide. Internally, in moderate dose, it is emetic; in sive quantity, an irritant poison, though again less t than the chloride. The salt is a favorite metallic astringent, being milder than copper or silver salts, of less harsh taste, and does not stain. It has thus a wide range of applicability, but yet, where a powerful action is wanted, it is distinctly inferior to silver nitrate or copper sulphate. The crystals are too small to permit the salt to be used in solid form; it is therefore used locally in solution, the strength ranging from the one-fifth of one per cent. to about four per cent. Dried zinc sulphate has been employed as a caustic, made into paste, with one-eighth part of glycerin, or into ointment with one-fourth part of lard. Internally, the salt—crystalline form—may be given for the constitutional effects of zinc, in doses of from 0.015 to 0.06 gm. (gr. ¼ to i.), several times a day; or as an emetic in doses of from 1 to 2 gm. (gr. xv. to xxx.).

Zinc Acetate ($Zn[C_2H_3O_2]_2$, $3H_2O$).—Zinc acetate is official in the United States Pharmacopœia as *Zinci Acetas*, Zinc Acetate. It occurs in soft, white, pearly, six-sided tablets and scales, which effloresce somewhat in dry air. It has a faint, acetous odor and a sharp, metallic taste. It dissolves in 2.7 parts of cold water and in 1.5 parts of boiling water; in 36 parts of cold alcohol and in about 3 parts of boiling alcohol. It should be kept in well-stoppered bottles.

Zinc acetate is practically a duplicate of the sulphate; but its use has been rather restricted by custom to local application for the purposes of the metallic astringents. Solutions may be employed of the same strength as of the sulphate.

Zinc Valerianate ($Zn[C_5H_9O_2]_2$, H_2O).—The salt is official in the United States Pharmacopœia as *Zinci Valerianas*, Zinc Valerianate. It is in soft, white, pearly scales, permanent in the air. It has a faint odor of valerianic acid, and a taste at first sweet, then styptic and metallic. It dissolves in about 100 parts of cold water and in 40 parts of cold alcohol. Boiling in either solvent determines loss of acid and the formation of a basic salt, with resulting turbidity of the solution. The salt should be kept in small, well-stoppered bottles. From its comparative insolubility, zinc valerianate is locally less active in every way than the salts typified by the chloride and sulphate. Its place in medicine rests upon the idea of combining in one drug the antispasmodic virtues of zinc and valerian; but since the effects of zinc are feeble at best, and valerianic acid is probably not the active principle of valerian root, there is little ground on which to rest a valid claim for the salt's efficacy. This valerianate also has the positive disadvantages of disagreeable smell and taste, and costliness. The salt has been given in doses of from 0.06 to 0.12 gm. (gr. i.-ij.) several times a day, best in pill.

Zinc Phosphide (Zn_3P_2).—This salt is of value solely as a means of giving phosphorus, and has been described under the title *Phosphorus*.

Zinc Nitrate ($Zn[NO_3]_2$, $6H_2O$).—Zinc nitrate forms by the direct action of nitric acid upon metallic zinc. It occurs in colorless prismatic crystals which are soluble in water and alcohol, and are very deliquescent. The salt is fusible, and has been employed, although it is unofficial, in the form of sticks of the fused substance cast in paper moulds, for application to sores and ulcers. The action is caustic and healing, after the manner of silver nitrate. Sticks of zinc nitrate must be kept dry in well-stoppered bottles, else they will be destroyed by deliquescence of the salt.

Zinc Oleate.—An oleate of zinc is obtainable in the form of a fine, soapy-feeling powder, of a pearl color. This powder proves to be a serviceable bland absorbent and detergent for local dusting upon the skin.

Edward Curtis.

ZINC-HEMOL. See *Hemols*.

ZINC, POISONING BY.—The most important salts of zinc, from a medico-legal point of view, are the sulphate and chloride.

Zinc sulphate, or *white vitriol* ($ZnSO_4, 7H_2O$), is a colorless salt, crystallizing in small four-sided prisms, which slowly effloresce in dry air. It is soluble in about two times its weight of water at the ordinary temperature, and in less than its own weight of boiling water; insoluble in alcohol, ether, and chloroform. Its taste is astringent and metallic; its reaction, acid.

Zinc chloride ($ZnCl_2$), commonly called *butter of zinc*, is a soft, white, very deliquescent, readily fusible solid, freely soluble in water and in alcohol. Its taste, in the solid state or in concentrated solution, is acrid and corrosive; in dilute solution, astringent and metallic. Its reaction is acid. When brought into contact with raw surfaces or mucous membranes it acts as a corrosive. It has considerable antiseptic power also, and, in aqueous solution, is frequently used as an antiseptic, deodorizer, and disinfectant. The liquid known under the name of "Sir William Burnett's disinfecting fluid" is such a solution, containing over two hundred grains of the salt in each fluidounce.

Cases of poisoning by these salts have been of rare occurrence and usually the result of accident. Zinc sulphate resembles magnesic sulphate (Epsom salts) very closely in its appearance, and has frequently been taken by mistake for the latter, while Burnett's fluid, which has been the cause of most of the reported cases of poisoning by zinc chloride, has frequently been mistaken for water or other harmless liquid.

SYMPTOMS.—Zinc sulphate acts as an irritant poison, but only when a large quantity has been taken. The symptoms are almost entirely local. The most prominent are: an astringent and metallic taste, burning pain in the œsophagus, stomach, and bowels, nausea, vomiting, purging, dyspnœa, small and frequent pulse, and cold extremities. The intellect usually remains clear.

The symptoms usually make their appearance almost immediately after swallowing the poison; but, in rare cases, they have been more or less delayed.

Wormley quotes a case in which vomiting was delayed for fifteen minutes, and there was no purging for ten hours. In this case a solution containing 46.5 gm. (℥ iss.) of the salt was swallowed. In a case communicated by Lutier active symptoms appeared first after the lapse of fifteen hours.

The symptoms produced by zinc chloride are similar in character to those just described. This salt has, however, a violent corrosive action, which is wanting in the sulphate. The local symptoms are therefore usually more severe than they are in cases of poisoning by the sulphate, and are more frequently followed by symptoms of profound collapse and death. In non-fatal cases recovery may not be complete until after the lapse of several days, or even weeks.

The investigations of C. Ph. Falck, Blake, Letheby, and Harnack show that the salts of zinc paralyze the striated muscles and cause death by their action on the heart and muscles of respiration, without influencing, to any great extent, the central nervous system. F. A. Falck, who experimented with rabbits, found that the temperature of the body is reduced 7°–13° C. in cases of acute zinc poisoning.

FATAL QUANTITY; FATAL PERIOD.—The quantity of any of the preparations of zinc required to endanger life is not exactly known. The sulphate is not a powerful irritant. In large doses it acts as a prompt emetic, and is frequently rejected by the stomach without producing any other serious symptoms. Quantities varying from 4.3 to 124 gm. (gr. lxvij. to ℥ iv.) have been taken without fatal result. Death has occurred in five hours (a child), thirteen and a half hours (adult, 5.8 gm.), thirty-six hours (7.6 gm.), three days (adult, quantity unknown), and five days (adult, 15.5 gm.). The chloride is much more dangerous than the sulphate. Most of the reported cases of poisoning by this salt have been caused by Burnett's solution, and the quantity taken has usually been known only approximately. Recovery has followed the administration of quantities of this solution varying from half a wineglassful to three fluidounces, the quantity of salt varying, so far as known, from 0.8 to 26 gm. (gr. xij.–cd.). Six and one-half grams (gr. c.) has caused death. Death usually takes place within twenty-four hours. The shortest fatal periods are two hours (Taylor), four hours (Allanson), seven and a half hours (Cousins), ten hours (Letheby). Occasionally the patient has recovered from the primary effects, only to succumb to the secondary effects after the lapse of several weeks. In such cases death usually results from starvation, following upon stricture of the œsophagus, pylorus, or intestines.

POST-MORTEM APPEARANCES.—When the sulphate has been taken, the lesions are substantially similar in character to those observed in cases of poisoning by other pure irritants. A slight ulceration, near the pyloric end of the stomach, has been noted in a single case. Rarely, there may be contraction of the stomach or intestines.

The chloride of zinc resembles in its action the mineral acids and caustic alkalies. In cases of poisoning by this salt the mucous membranes of the mouth, throat, œsophagus, stomach, and intestines are usually more or less disorganized. In a few cases, however, there has been an absence of corrosion even in the mouth. Perforation of the stomach, and stricture of the œsophagus, pylorus, and intestines may be met with, especially in cases which are not rapidly fatal. Congestion of the brain and its membranes, and of the lungs and kidneys, are usual sequels of acute poisoning.

TREATMENT.—Vomiting should be encouraged if necessary. Sodic carbonate precipitates zinc carbonate from solutions of soluble zinc salts and may therefore be employed as a temporary chemical antidote. In other respects treatment must be symptomatic.

OTHER COMPOUNDS OF ZINC.—The remaining soluble salts of zinc are substantially duplicates, in their effects, of the sulphate or chloride.

Zinc oxide and *zinc carbonate* are white amorphous solids, insoluble in water, but soluble in dilute acids, the carbonate dissolving with effervescence. Either of these compounds, if taken internally in considerable quantity, may dissolve in the fluids of the stomach and intestines and give rise to acute or subacute poisoning, with the usual symptoms of irritant poisoning.

Chronic zinc poisoning has been ascribed to the long-continued inhalation of the vapors of zinc oxide. This form of poisoning has been observed in workers in zinc, brass, and galvanized iron, and is characterized by headache, chilliness, pains in the extremities, a strong metallic taste, nausea, vomiting, diarrhœa, and colic. It is to be borne in mind in this connection that commercial zinc usually contains lead, and frequently arsenic, and that the above symptoms may be those of poisoning by one or the other of these metals, and not by zinc oxide.

The use of galvanized iron pipes for conveying water, and of galvanized iron utensils for the preparation and storage of food, appears to be attended with some danger. Water that has passed through galvanized iron pipes almost always contains zinc compounds, either in solution or in suspension. There is some difference of opinion as to the effect of such water on health, but it is generally believed that the danger of poisoning from the zinc in solution in the water is very slight. When the water has stood in contact with the pipe for several hours it frequently holds in suspension a considerable quantity of insoluble zinc compounds. It seems probable that the use of such water would be attended with danger. As a precautionary measure, therefore, the water that has stood in contact with a galvanized iron pipe for several hours should be allowed to run to waste, or should be filtered before use.

Certain liquids used in cooking, especially such as contain vegetable acids, may dissolve a sufficient quantity of zinc from galvanized iron utensils to produce symptoms of poisoning. Wormley reports a case of zinc poisoning caused by the use of apple butter prepared with cider which had been concentrated in a galvanized iron pan. The concentrated cider was found to contain 1.14 grains zinc oxide to each fluidounce.

ABSORPTION AND ELIMINATION.—When compounds of zinc are taken internally the metal is absorbed, presumably in the form of albuminate, and may be detected, after death, in the blood and in all the tissues of the body. Matzkewitsch administered the acetate of zinc to dogs by subcutaneous injection, and found, as the result of five experiments, that the greater proportion of the zinc thus introduced was localized in the muscles and bones. The skin, brain, liver, heart, lungs, kidneys, bladder, stomach, and intestines contained zinc, but in relatively small quantities. Zinc is eliminated with the urine, bile, and milk (Falck, Harnack). According to Michaelis the metal is first detected in the excretions on the fourth or fifth day after the administration of its compounds. The time required for complete elimination is unknown. According to Popoff it can be detected in the urine for months after removal from its influence.

The study of the localization and elimination of zinc is attended with peculiar difficulties, inasmuch as the human system frequently contains small quantities of the metal even when its compounds have not been purposely administered. Raoult and Breton isolated 7 mgm. of zinc from 700 gm. of human liver in one case; 12 mgm. from 400 gm. of liver in a second case. In four other cases they extracted 10, 30, 34, and 76 mgm., respectively, from 1,000 gm. of liver. Lechartier and Bellamy obtained similar results. In one case 1,780 gm. of liver contained 20 mgm. of zinc oxide. The same authors extracted 30 mgm. of zinc oxide from 913 gm. of muscle from the ox, and 20 mgm. from 1,152 gm. hard-boiled egg. They also detected traces of zinc in corn, maize, barley, and white beans.

The frequent presence of small quantities of zinc in the organs of the body may be explained in some cases by the use of water which has been conveyed through galvanized iron pipes, or by the use of food which has absorbed zinc from galvanized iron utensils; in other cases, by the medicinal administration of preparations of zinc before death, or the introduction of embalming fluids containing salts of zinc, after death.

In consideration of the foregoing facts it is obvious that the detection of zinc in the tissues after death cannot, when unsupported by other evidence, be accepted as proof that death was caused by zinc poisoning.

ZINGIBER. See *Ginger.*

ZONIAN SPRINGS.—Kane County, Illinois.

These springs are three or four in number, and are located one mile north of the city of Elgin, in a fine, wooded, rolling country, about 2,000 feet above the sea-level. The atmospheric temperature varies from about 75° to 80° F. during the summer, and from 10° to 60° F. during the winter months. The following analysis of the water was made by J. E. Seibel, analytical chemist, Chicago:

One United States gallon contains (solids): Calcium carbonate, gr. 9.56; iron carbonate, gr. 0.49; magnesium carbonate, gr. 2.49; sodium carbonate, gr. 0.45; sodium sulphate, gr. 1.75; sodium carbonate, gr. 0.70; silica and aluminum, gr. 0.26. Total, 15.69 grains.

It is stated that the water also contains a considerable amount of free carbonic acid. The flow of water amounts to about one barrel per minute from each spring. Kidney, stomach, and liver troubles are said to be benefited by the waters.

James K. Crook.

ZYMASE.—In 1897 E. Buchner demonstrated that the phenomena of alcoholic fermentation can be brought about without the presence of living yeast cells or other organized ferments. By subjecting yeast which has been ground up with sand, kieselguhr, and water to a pressure of four hundred to five hundred atmospheres it is possible to collect a fluid free from protoplasmic particles or living matter in any form. When this juice is brought into contact with strong sugar solutions it provokes a vigorous evolution of carbon dioxide (CO_2), alcohol ($C_2H_5.OH$) being simultaneously formed in the mixture. The reaction proceeds unaltered even in the presence of one-per-cent. sodium arsenite or of chloroform and other substances which readily destroy micro-organisms. The activity of the juice is lost by heating above 40°–50° C. From these facts it follows that the reaction is attributable to an enzyme to which the name *zymase* has been given. Despite the vigorous criticism which the announcement of this discovery speedily provoked, it is now firmly established that ordinary alcoholic fermentation is not a "vital" process of the yeast cell, but is brought about by the intermediation of soluble enzymes. The change which sugars undergo in the presence of yeast has always been pointed out as a typical "fermentation" reaction, in distinction from "zymolytic" (enzymatic) transformations. Accordingly the detection of zymase will emphasize more than ever the wide distribution and significance of enzymes in the life processes; and we may almost confidently expect sooner or later to find a specific enzyme for every vital chemical reaction.

Zymase is already known to occur widely in nature. The observations of Buchner on the yeast have repeatedly been verified; Mazé has isolated zymase from fungi; and Stoklasa and his co-workers have demonstrated its occurrence in many of the higher plants like the sugar beet, as well as in various animal tissues. The importance of this for the carbohydrate metabolism and internal respiration of both animals and plants can as yet scarcely be foretold. It is impossible at the present time, however, to assert that the zymases isolated from the various sources referred to are identical. As far as has been investigated the products of the reaction occur very nearly in the proportions demanded by the equation $C_6H_{12}O_6 = 2C_2H_5.OH, + 2CO_2$, only small quantities of side products being found. It seems likely that one of these, lactic acid, owes its existence to the activity of a specific enzyme.

Zymase may be isolated by the method of Buchner and Albert. The intracellular juices obtained by the method already indicated are treated with alcohol and ether, and the precipitate containing the enzyme is dried at a low temperature. The details of the method as applied to various animal and vegetable tissues must be consulted in the original papers. The glycolytic enzyme in animal tissues like the heart, lungs, etc., may also be demonstrated by immersing the sterile tissue in a sterile sugar solution in an atmosphere of hydrogen. The evolution of CO_2 and the formation of alcohol are then readily demonstrated. Experiments of this sort serve to awaken interest in the possible formation of alcohol in the intermediary metabolism of animals.

Although dried preparations of zymase retain their glycolytic properties for a long time, solutions of yeast zymase soon lose their power if a proteolytic enzyme (like yeast endotrypsin) is simultaneously present. Compared with equivalent portions of yeast, the cellular juices containing zymase are less efficient as fermentative agents. This is doubtless attributable to the constantly renewed production of enzyme in the case of the living cells. Zymase may readily be demonstrated in carefully dried yeast in which all the cells are dead. A method for making a permanent sterile preparation of this sort by the use of acetone (Aceton-Dauerhefe) has been devised by Albert.

Lafayette B. Mendel.

LITERATURE.

A review of the literature on the zymase of yeast will be found in Die Zymasegährung, von Ed. und Hans Buchner und Martin Hahn, München, 1903. Further:

ZYMOGENS.—This generic name has been applied to the precursory stage in which the enzymes are present in the cells of secretory glands. In this condition, there is no activity, but in the process of secretion, or in some instances after the secretion is thrown out upon the mucous surface and has come in contact with activating substances present in other secretions with which it is mixed, the zymogen undergoes a chemical change, the nature of which is unknown, by which the active ferment is formed. Such a conversion into active ferment can also be produced artificially in many instances by treating the fresh gland with very dilute acetic acid, or it occurs spontaneously on allowing the gland to remain for some hours after removal from the body, especially if it be kept during this interval at body temperature.

The presence of zymogens has been known now for many years, and recently great advance has been made in our knowledge of the conditions under which they are set free (see for example, enterokinase, in the article on *Pancreas, Physiology of*).

For further information on zymogens, see the article on *Enzymes*. *Benjamin Moore.*

ZYMOLYSIS.—This is a general term used to designate the changes produced by enzymes. See articles on *Digestion*, on *Enzymes*, and on *Pancreas*. *B. M.*

APPENDIX.

ALASKA.—This vast northwestern possession of the United States, extending over 16 degrees of latitude and 35 degrees of longitude, and embracing 590,884 square miles of territory, equal to nearly one-sixth of the area of the United States, exhibits a variety of climatic conditions and contrasts dependent not only upon latitude, but upon the topography of the country and the influence of the surrounding waters and currents. Two great climatic divisions can be made: southern or temperate Alaska, which can be subdivided into the Sitka, Kadiak, and Aleutian divisions, and northern Alaska or the Yukon district, embracing the vast region to the north and west of the Alaskan Mountains.

The climate of temperate Alaska is characterized by two striking peculiarities: comparative warmth and great moisture, caused by the Kuro Siwo, the "Gulf Stream" of the Pacific. This current crosses the Pacific in about latitude 45° N., and impinges on the coast of British Columbia where it divides, one portion turning northward and westward and the other southward. As a result of this condition, the temperature is greatly modified from what the latitude alone would lead one to expect, exactly as the climate of Great Britain, for example, is modified by the gulf stream. The isotherm of 40° mean annual temperature, that of the lower St. Lawrence valley, is the mean annual isotherm of the Southern Alaskan coast region. Sitka, with a latitude of 57.03°, which is the same as the latitude of Labrador on the Atlantic coast, has a mean annual temperature of 43.9° F., which is only 2.6° lower than that of Portland, Me., and a mean winter temperature of 32.5°, which is 6.9° higher than that of Portland, and only a little less than that of Washington, D. C. The extreme range of temperature is from a point a trifle below zero to 90° above. Similarly, Juneau, in the Sitka district, northeast from Sitka, has a mean annual temperature of 40.9° F. The annexed chart of the maximum, minimum, and mean temperatures of Juneau and Sitka for the year indicate still further the moderate temperature of the region.

The second peculiarity of temperate Alaska is moisture in the form of rain or fog, and in the Sitka division, which extends from Dixon Entrance to William's Sound, the yearly rainfall is from eighty to one hundred and three inches, and there are on an average but sixty-six clear days in the year. "When the sun shines, the atmosphere is remarkably clear, the scenic effects are magnificent, all nature seems to be in holiday attire. But the scene may change very quickly; the sky becomes overcast; the winds increase in force; rain begins to fall; the evergreens sigh ominously, and utter desolation and loneliness prevail." [United States Department of Agriculture, Weather Bureau.] The Sitka district is very mountainous, and the coast bold and steep with few beaches. The mountain sides are densely wooded, and the snow line begins at an elevation of from three thousand to five thousand feet. The prevailing winds being westerly and off the ocean, bring the moisture to the snowy mountains, which condense it. Hence it is the combination of the mountains, the prevailing moist winds from the sea, and the warm Japan current, which results in this enormous rainfall, nowhere else equalled in the United States, the annual rainfall at Sitka being more than double that on the Atlantic coast. At Sitka the rainfall for the three winter months is about thirty inches, and for the three summer months sixteen inches.

The Sitka region is the scenic portion of Alaska, visited by tourists, and here are found immense glaciers descending into the ocean.

The country is heavily wooded with spruce, hemlock, and cedar, and the vegetation is dense. On account of the sparse sunshine agriculture is difficult, but many garden vegetables are successfully grown.

In the Kadiak district, which comprises Cook's Inlet, the peninsula of Alaska, and the Kadiak Islands, the climate is similar to that of the Sitka region, but there is more sunshine and less rain, and the seasonal extremes of temperature are greater. At Kadiak the annual mean temperature is 40.6° F., and the number of days of rain or snow for ten months of the year 1899 was 133, and the number of cloudy days 124, making 257 cloudy and rainy days out of 304. The monthly mean temperature at Kadiak for eight years is as follows:

KADIAK—LAT. 57° 48′; LONG. 152° 19′. MONTHLY MEAN TEMPERATURE (DEGREES FAHRENHEIT) FOR EIGHT YEARS.

January	30.0	August	55.2
February	28.2	September	50.0
March	32.6	October	42.3
April	36.3	November	34.7
May	43.2	December	30.5
June	49.5	Year	40.6
July	54.7		

In the Aleutian district, comprising the range of Aleutian Islands, the range of temperature is much the same, as the following chart of Unalaska indicates:

UNALASKA—LAT. 53° 54′; LONG. 166° 24′. MONTHLY MEAN TEMPERATURE (DEGREES FAHRENHEIT) FOR SIX YEARS.

January	30.0	August	51.9

According to Harriman (Alaskan expedition), there were at Unalaska only 8 days in the year, during several years' record, which were entirely clear, the remaining 312 being cloudy and 271 of these were rainy or snowy.

The Yukon district, or Northern Alaska, comprises that vast region of the Yukon Valley which extends from the Alaskan Mountains to the Arctic Ocean on the north and Behring Sea and Strait in the west.

In the interior of this region the climate becomes colder and drier—extremely rigorous during the long winter and relatively hot in the short summer. As one continues north arctic conditions of climate begin. On the Behring Sea coast, north of the Aleutians Islands, the winter climate is much more severe than that of temperate Alaska on the Pacific coast, but in summer the difference is less marked. At St. Michaels, on the south side of Norton Sound, the mean summer temperature is 50° F., which is but 4° below that of Sitka; and at Point Barrow, on the Arctic Ocean, the most northerly point in the United States, the mean summer temperature is 36.8° F. Furthermore, the winter on the Behring Sea coast about the mouth of the Yukon River and the Seaward Peninsula is somewhat less protracted and severe than in the interior, although it is still long, and from October to May the temperature rarely rises above the freezing point.

Extreme cold, however, as one knows from the experience of Arctic explorers, is not detrimental to health, and at Nome, the most populous mining town in Alaska, the winter is said to be the most agreeable season of the year, in spite of the fact that in midwinter there are but few hours of daylight, the shortest days giving but about three and a half hours of dusky light. "With hands and feet warmly protected, and winter underwear and windproof outer clothes *and exercise*, one can comfortably weather a degree of cold which, in lower latitudes, would immediately transform him to an icicle. This is due to the dryness of the cold." ("The Land of Nome," by Laurie McKee, New York, 1902.)

The following table, compiled from observations of the United States Weather Bureau, gives the annual and monthly mean temperatures and the extremes for St. Michaels, which is on the southern side of Norton Sound; it also may be utilized for ascertaining approximately the yearly temperature of Cape Nome, which is one hundred and fifty miles distant on the northern shore of Norton Sound, at its junction with Behring Sea. In the same table will be found a statement of the mean number of rainy and snowy days. As will be seen, the rainfall is very light, and is about fourteen inches annually, a striking contrast to that of Southern Alaska.

One cannot be sure of reaching Nome by sea much before the middle of June on account of the ice in Behring Sea, or of getting away from there after the latter part of September or 1st of October. The prevailing winds are from the north, and severe blizzards with strong northeast gales are frequent in winter. In comparing the climate of Nome with that of the Klondike region to be spoken of directly, it may be said that in general the climate of the latter is rather more favorable than that of the former. The most trying climatic element is the continual wind.

Fifteen hundred miles in the interior, to the east of Nome City, is the Klondike region, also famed and frequented for the gold discovered there. It is reached either overland—the common passenger route from Skagway by rail for about one hundred miles by the White Pass and Yukon Railroad, and thence by steamer on the upper Yukon to Dawson—or by the longer all-water route, which is principally used for freight, by way of the lower Yukon. The distance from Skagway to Dawson, the principal city of the Klondike (in Canadian Territory), is five hundred and eighty miles.

The general characteristics of the Klondike climate are similar to those of Nome—long, extremely cold winters, with much snow and "brief but relatively hot summers." "In midwinter the sun rises from 9:30 to 10 A.M., and sets from 2 to 3 P.M., the total length of daylight being about four hours." (United States Weather Bureau report.) In June the sun rises about 1:30 in the morning and sets at 10:30 P.M., "giving about twenty hours of daylight, and diffuse twilight the remainder of the time." "During the warmer days of summer the heat feels almost tropical; the winter cold is, on the other hand, of almost the extreme Siberian region." "Yet a beautiful vegetation smiles not only over the valleys, but on the hilltops, the birds gambol in the thickets, and the tiny mosquito pipes out its daily sustenance to the wrath of man." (Heilprin, "Alaska and the Klondike.")

The following observations of mean and extreme temperatures of the United States Weather Bureau made at the Yukon River at the international boundary, about eighty miles north of Dawson, from September, 1889, to June, 1891, will indicate approximately the temperature conditions of the Klondike.

From observations made on the Yukon, not far fro
the site of the gold discoveries, by the United Stat
Coast and Geodetic Survey for a series of six months, t
following temperatures are noted: From October, 18
to April, 1890, the mean temperature was as follo
October, 33° (above zero); November, 8° (above zer
December, 11° (below zero); January, 17° (below ze
February, 15° (below zero); March, 6° (above ze
April, 20° (above zero). "The daily mean temperat
fell and remained below the freezing point (32° F.) fr
November 4th, 1889, to April 21st, 1890, thus giving
hundred and sixty-eight days as the length of
closed season. The lowest temperatures registered d

indiscriminately throughout the city. The instance is interesting, because while the inhabitants remained in the Faubourg du Puirault, the disease stayed there, whereas, as soon as they scattered, it spread with them throughout Chatillon.

Another instance, interesting as an example of the transmission of the disease by clothing, is given by the same authority, in speaking of the Commune of Oussoi. Madame Bresson, of the hamlet of Moulineuf, near Oussoi, a precinct free from cholera, received a boarder from Paris, June 27th, who on the next day showed the first symptoms of cholera, and died on July 3d. Some days after, a child of this woman was attacked and died on July 13th. On the same day Madame Bresson herself was taken sick, and died on the 17th, after having been taken care of by two neighbors named Sahan and Moret, who died, one on the 16th and the other on the 24th. The husband of Madame Bresson died on July 26th. Madame Burette, who lived in the extreme end of the hamlet, washed the linen of the two women, Sahan and Moret, and was attacked with cholera. In this way, an epidemic was started that carried off eighteen persons in a very short time. Before the arrival of the person from Paris no case had been observed in this hamlet, that had been spared by the cholera both in 1852 and in 1849. Dr. Huette calls attention to the distribution of this hamlet of Moulineuf, which is composed of ten little collections of houses, separated by great distances. No cases of cholera were observed excepting in three of these collections of houses—first, that occupied by the Bresson and Sahan families; second, that occupied by the Moret family; and third, that occupied by the Burette family. The third collection of houses was situated at the extremity of the hamlet. No case of the disease was observed in the other houses, of which the inhabitants had had no connection with these three families.

Proust (*loc. cit.*, p. 165) quotes an occurrence illustrating another series of facts.

In 1854 the French army was collected at Varna, a short distance from the English army. Some detachments remained at Gallipoli, the original place of debarkation. There were, besides, a small Anglo-French force of occupation in the Piræus, and also some detachments at Constantinople. The armies were reinforced practically every day by new arrivals. The sanitary condition was satisfactory in all respects. On July 5th the packet *Alexandre* arrived at Constantinople, having left Marseilles on June 26th with five hundred men of the Fifth Regiment of Light Infantry, coming from Montpellier, and having passed through Avignon, where cholera was raging. It appeared on board, and three men died during the voyage to the Dardanelles. Four cholera patients were landed at the Piræus, where the cholera broke out immediately, and made great ravages. The troops were disembarked at Gallipoli, where two new cases of cholera were immediately sent to the hospital, and the ship, having only a few passengers on board, sailed for Constantinople, where a quarantine was imposed on it. On the other hand, it appeared that previous vessels sailing from Marseilles had already suffered from cholera, and that one of them had landed a patient in the military hospital at Constantinople. On July 15th, after new arrivals of cholera patients, the disease spread at Gallipoli, and there appeared in the military hospital of Constantinople a choleraic focus. Fauvel, struck by the danger, proposed, and had adopted by the Council of Health at Constantinople, a momentary interruption of the communication between Gallipoli and Varna. The measures prescribed were not executed, and in spite of the insistence of Fauvel before the Marshal de Saint Arnaud, many ships sailing from Gallipoli passed the Bosphorus and went directly to Varna, where free pratique was accorded them. Cholera then broke out in the army among the newly arrived soldiers and in the hospital. On Au[illegible] [illegible]th the epidemic was violent at Varna, especially [illegible] the troops sent into the Dobrudja. The English [illegible] was invaded, having the epidemic on board [illegible] the Crimea, the epidemic, mistake of a servant who gave him a bottle of wine containing arsenic intended for Cardinal Corneto. Alexander left two of his five children, Lucretia and Cæsar Borgia, of hideous memory, demons in human form, to distribute arsenic in all directions. About this time arose the famous Council of Ten of Venice, spreading murder abroad largely through the agency of an adept in the use of arsenic, de Ragubo, the Franciscan.

A century later makes us acquainted with the celebrated "Acqua Toffana," which probably consisted of a solution of arsenic trioxide in aqua cymbalaria, to which a small amount of tincture of cantharides was added. The woman Toffana, living in Palermo and Naples, discoverer and dispenser of this liquid, is credited with the death of over five hundred victims, including several crowned heads and two popes. While she practised her nefarious trade for years unsuspected, the Acqua Toffana struck terror throughout all Italy, and even throughout France and Austria. After her detection she fled for safety to a convent, where for twenty years longer her horrible trade flourished in secret. Upon her final detection and execution La Toffana's clients were supplied with the arsenical fluid by Spara, who had obtained the secret of its preparation from Toffana. Spara sold her preparations under a variety of other names, as, for example, "Manna di S. Nicolas di Bari," "Acquetta di Napoli," etc. Since Spara's clients seem to have been mostly of the middle class, records are lacking as to the extent of her criminal practices. Toffana and Spara also prepared and dispensed another poison even more potent, in which arsenic was combined with putrefactive compounds (the arsenical ptomaïns of Selmi). This preparation, sold under the name of "Acquetta di Peruzia," was prepared by sprinkling the viscera of a freshly killed pig with white arsenic, hanging them up and then collecting in a vessel the drippings of the putrefying material.

France now became the theatre of the great arsenical crimes of history through Catherine de Medici, who brought with her to France arch poisoners from her native land. The court of Louis XIV. was fairly smothered in crime. Among the hundreds of petty poisoners two remarkable women, doubtless the greatest criminals France has ever seen, stand head and shoulders above the rest. The first of these, Marguerite d'Aubray, Marquise de Brinvilliers, angelically beautiful, with winning voice and saint-like appearance, yet addicted to unspeakable vices from a child up, had been taught the methods of mixing arsenic with foods and beverages by her paramour Saint Croix. This woman had set her heart upon inheriting the family estate, and to gain her end it became necessary to cause the death of her father, brothers, and sister. In order to accomplish this she obtained entrance to the great hospitals of Paris under the guise of a Sister of Mercy. Here as a nurse she administered arsenic with food and medicine, noted the effects, going each day to the internes to learn the progress of the disease. Finding that her practices were unsuspected and undetected, she carried her experiments still further by giving arsenic in food to the poor who called at her door, dosing her servants and visiting the hospitals to which they were taken in order to learn the effect. Having at last satisfied herself that she knew the dose and the rate at which the poison should be administered, she proceeded with the execution of her long-planned crime. During a period of over eight months she administered arsenic to her father, thirty times by her own hands and a number of times by a servant. At the end of this period the murder was accomplished by giving a double dose. In a like manner she disposed of two brothers and attempted the life of her sister. If her servants displeased her, a little arsenic, carefully dispensed, put them out of her way. It has been impossible to ascertain the number of her victims, so cunningly did she work. Not only did she use arsenic trioxide alone, but also a carefully compounded mixture of this substance with mercuric chloride. Her crimes being discovered upon the death of Saint Croix, she was tried, found guilty, and executed in July, 1676. Thus it was that the Marquise de Brinvilliers invented the infamous "poudre de succession," which in the hands of the second of the women, La Voisin and her accomplices, literally powdered Paris and part of France with arsenic.

The revolting story of La Voisin is foreign to the topic under discussion. Suffice it to say that the poison she dispensed was generally white arsenic; but what is noteworthy, is that she followed the de Brinvilliers' method, which had been experimentally developed, namely, slow poisoning. Poisoning became such an epidemic in France, following the publicity of these cases, that the notorious special court (La Chambre ardente—Court of Poisoners) was established. This body proceeded so perseveringly, thoroughly, and mercilessly that since 1682 there have been no systematic poisonings by professional poisoners, clubs, or bands. It has been recently stated that in modern times no Locusta, Toffana, nor de Brinvilliers can exist, that the illness of the victims would promptly be diagnosed as arsenical poisoning and the criminal discovered. Unfortunately, this belief is not justified, for there are many cases which demonstrate that slow poisoning by arsenic is not readily diagnosed. Take, for example, the case of the monomaniac Hélène Jegado, who from 1833 to 1852 poisoned some 47 persons, about 30 of whom died, all of arsenic poisoning; or again there is the woman Van der Linden, who in 1887, acting as a nurse and at the same time agent for an accident insurance company, poisoned, or attempted to poison, 102 persons. Twenty-seven died; 47 were made seriously ill. As a nurse she dosed her victims, in whose names she herself had made out policies. In due time she collected from the company the amount of the policy for illness or death. So carefully did she proceed that the illness of her victims was not diagnosed as arsenicism. Again, take the cases of great mass-poisoning by wine containing arsenic at Hyères in 1887, due to the circumstance that a wine merchant, with the intention of plastering his wine, had dropped into the fermentation vat by mistake a quantity of white arsenic. There were over 400 victims and 4 deaths. All sorts of diagnoses were made by the physicians, and it was not until many months afterward that the true cause was discovered. Similar errors were made in 1900–02 in the famous beer poisonings in Great Britain. In this epidemic there were over 4,000 victims and 300 deaths. The first cases of illness were reported in the latter part of April and early in May, but it was not until the following November, seven months later, that the proper diagnosis of arsenical poisoning was surely established, and it was shown that the trouble came from impure sulphuric acid used for the inversion of sugar and starch, which materials under the Gladstone bill could be used for the manufacture of beer.

Within a few months two cases of slow poisoning by arsenic have come to the author's attention, in each of which the attending physician failed properly to diagnose the illness. One of these cases was homicidal.

The lessons to be drawn from the historical cases and others cited above seem quite plain. The physical diagnosis of subacute or chronic arsenical poisoning is often uncommonly difficult.

MOST IMPORTANT COMPOUNDS WITH REFERENCE TO POISONINGS.—*Arsenic trioxide*, As_2O_3 (synonyms: arsenious acid, arsenious anhydride, white arsenic, arsenic, ratsbane, rough-on-rats, etc.) exists in two allotropic modifications, the amorphous and the crystalline. The crystalline form is of a dead white, opaque, and porcelain-like appearance; the amorphous, on the other hand, is clear, transparent, and glass-like, and for this reason is often termed vitreous, and has a tendency to pass slowly into the crystalline state. Because of this change, commercial samples of lump white arsenic are mixtures of the two modifications. Save in India, where it is sometimes colored yellow with cow's urine, arsenic trioxide occurs in commerce as a heavy white powder, or in the form of opaque white lumps, which when broken show a transparent glassy centre. The solubility of the commercial samples varies within quite wide limits; this is due to the fact that the solubility of the two modifications of As_2O_3 are different, that of the pure crystalline being about 1 in 350 of water at 15° C., and that of the pure amorphous 1 in 108. Cooled from boiling, 1 part in 45 of the crystalline remains in solution and 1 part in 30 of the amorphous. No two observers agree, however, as to the solubility of As_2O_3.

Arsenites.—All the samples of commercial dry arsenite of sodium and of potassium which have been examined by the author seem to correspond most closely to the formulas $NaAsO_2$ and $KAsO_2$. Their solubility in water is quite variable, but is always much greater than that of the trioxide. The majority of cases of poisoning from alkaline arsenites have been from the medicinal preparations of these salts, such as Fowler's solution, etc. Only a very few of these cases have been criminal.

Arsenates.—These salts correspond to the general formula R_3AsO_4. They are of little toxicological interest save for the fact that arsenic acid has been largely used in certain industries (*e.g.*, manufacture of aniline dyes) as an oxidizing agent, and the products placed on the market in an impure condition contain arsenic in enormous quantities.

Sulphides of Arsenic.—The disulphide, As_2S_2, occurs in nature as realgar, and was known to the ancients under the name sandarac or sandaracque. Realgar, both the mineral and the artificial compound, has been used as a pigment, in pyrotechnics, etc. The trisulphide, As_2S_3, long known as the mineral orpiment or auripigment, has had a variety of commercial uses. It was formerly used in printing, in tanning as a depilatory, in medicine, as a pigment, etc. The pentasulphide, As_2S_5, is of no medicinal importance. All the sulphides met with in commerce are amorphous yellow powders, varying in color from a light lemon yellow to a deep golden or even orange tint. When pure they are insoluble in water, hence their toxicity is very low. Some authorities hold that the pure sulphides are not poisonous. Experimental evidence shows, however, that these compounds are acted upon by the fluids of the body, and that arsenic is resorbed. Doubtless a long sojourn of these sulphides in the alimentary canal would lead to serious results. The commercial sulphides are invariably violent poisons, since they contain arsenic trioxide, sometimes to the extent of as much as thirty per cent. Le Prince and Chabenat report the case of a young girl who used an ointment consisting of 65 parts of butter and 35 parts of orpiment as a dressing for a tumor of the breast. Acute arsenic poisoning resulted, with death on the fifth day after the application of the dressing. As a depilatory, orpiment has been used from earliest times. It was a mixture of orpiment with lime or chalk, which was used by the ancients for the removal of the pubic hairs—a practice said to be still extant, at least in the case of women, in certain Mussulman tribes of the East.

Cases of poisoning from organic compounds of arsenic have not yet been reported, if we except those due to the notorious Acquetta di Peruzia. But considerable experimental work has been done on animals with kacodyl, kacodylic acid, diphenylarsine, monophenylarsine, arsendimethylcyanide, etc.

Coloring matters, pigments, containing arsenic, are responsible for a large percentage of cases of poisoning, both acute and chronic. Scheele's green (synonym· mineral green, Swiss green) is copper arsenite of somewhat variable composition. It is insoluble in water, and corresponds to the formulas $CuHAsO_3$ or $Cu_3(AsO_3)_2 2H_2O$. This beautiful compound is used as a pigment in painting, printing, etc., and as an insecticide. Paris green (synonyms: Vienna green, mitis green, Schweinfurter green) is a double salt, copper aceto-arsenite, corresponding to the formula $Cu\,(As_2O_4)_3,Cu(C_2H_3O_2)_2$. The commercial product is of variable composition according to the method employed in its manufacture. It is now used in enormous quantities as an insecticide; rarely as a pigment in painting, coloring, etc. Aniline dyes of the rose-aniline group, which have been made by the old arsenical process, usually contain arsenic in large amount. The most important of these are the magentas and reds, but the blues, violets, purples, etc., may also be arsenical. In fact, it may be said that there is scarcely a shade which cannot be obtained by blending arsenic-containing dyes. Practically all the manufacturers of aniline dyes have now abandoned the arsenical process, but the author is informed that there is still one firm in New York State that uses arsenic acid in the preparation of fuchsin. Closely related to the aniline dyes are the arsenical lakes, such as Cochineal red, Vienna red, etc. King's yellow consists of impure arsenic trisulphide, hence is essentially orpiment. It often contains eighty to ninety per cent. As_2O_3. Mineral blue, a pigment in which copper arsenite and potassium arsenite enter in about equal parts, contains about thirty-nine per cent. arsenic.

Arsenical insecticides are responsible for a large number of deaths, accidental, suicidal, and criminal. Of these substances the most important is Paris green. Its composition and quality are now controlled by statutory enactment in several States of the Union. When sold as an insecticide the statutes call for a product containing combined arsenic in an amount which shall be not less than fifty per cent. calculated as As_2O_3, not over four per cent. of which shall be soluble in cold water. Most of the cases of poisoning by this material occur in the United States and in Russia. London purple (synonyms: English purple, Paris purple), formerly much used, is obtained by treating a by-product of the aniline dye industry with lime. The arsenic is present both as calcium arsenite and as calcium arsenate, the latter in excess of the former. Calculated as arsenic the average amount present in London purple is about twenty-nine per cent. Arsenoids, substitutes for Paris green, have been placed on the market in recent years. Green arsenoid contains on an average about sixty per cent. As_2O_3, and has been incorrectly called Scheele's green. White arsenoid contains barium arsenite; thirty-three per cent. of the arsenic present is water-soluble. Para green is a mixture of Paris green with about thirty-six per cent. gypsum. Laurel green consists essentially of calcium arsenite (thirteen per cent.), gypsum, calcium carbonate, and magnesum carbonate.

Vermin Killers.—Of the many arsenical poisons on the market for the purpose of destroying rats, mice, etc., only one needs discussion, *i.e.*, rough-on-rats. This preparation has been employed in many crimes in the United States and consists of arsenic trioxide about seventy-two per cent., barium carbonate twenty-six per cent., sand two per cent., with usually a little carbon to color it. In case of a question of poisoning by this vermin killer, barium should always be searched for. The author has, however, in his possession a sample of this material purchased some years ago which contains no barium.

Arsenic in Foods, Beverages, etc., occurs (1) as a preservative, (2) in coloring matter added, or (3) as an accidental impurity. In official reports issued by the German Government the claim is made that there are annually exported from the United States to European ports enormous quantities of dried apples which have been treated with weak arsenical solutions to preserve them from decay and from the attacks of insects. Moscow, Russia, suffered severely some years ago from a cholera-like epidemic, the cause of which was eventually traced to sturgeon flesh which had been sprinkled with white arsenic to arrest decomposition. The addition of arsenical colors to foods and beverages has given rise to a large number of cases of arsenical poisoning. Sausage, jellies, preserved fruit, wines, fruit syrups, confectionery, cakes, etc., have all been found to have caused trouble. Usually this has been due to arsenical aniline dyes, but in a few instances Paris green has been present. Accidents arising from the presence of arsenic as an impurity in some product used in the manufacture of the food or beverage are usually confined to beers, ales, or glucose preparations. While we are considering poisonous food materials, the fact must not be overlooked that cattle feeding in the neighborhood of industries throwing out arsenic may become poisoned or else relatively immune from habitual use, and their flesh when eaten by man may lead to very serious results. The same holds true for milk secreted by an animal which has taken arsenic into its system.

Arsenic in Colored Papers, Inks, Clothing, etc.—Many cases of very serious chronic arsenical poisoning have been traced to these sources. A decade ago the amount of highly arsenical wall papers was appalling, and in spite of the denial of eminent chemists and hygienists, the evidence is such that chronic poisoning from arsenical wall papers must be accepted as an established fact, providing that the room so papered is small, damp, and ill ventilated, and the alleged victim spends much time in the room. Contrary to popular opinion, green-tinted papers are rarely arsenical; those which have caused trouble in the United States have almost invariably been tinted in shades of red. In an investigation conducted by the author some years ago upon an undoubted case of arsenicism from wall paper, it was found that over ninety per cent. of the red and maroon papers obtainable of the same date of manufacture as that on the walls of the room were highly arsenical. Many samples of wall papers manufactured within the last six years have since been examined, but none of these modern papers have thus far been found which contain more than mere traces of arsenic. In all probability the cause of arsenicism from wall papers is largely due to the formation, by moulds and bacteria, of arsine and of a volatile organic arsenic compound. This peculiar action is so well marked in the case of Penicillium brevicaude that advantage is taken of the fact for the purpose of testing for the presence of arsenic. Mucor mucedo, Aspergillus glaucus, Aspergillus virescens also possess this same property, but to a less degree. Colored papers other than wall papers have also given rise to poisoning: as, for example, the chewing of such papers by children, the moistening with the tongue of many colored gummed labels. In 1889 several cashiers in German banks were poisoned through handling with moistened fingers large numbers of Swiss banknotes printed with arsenical ink. Several cases are on record of poisoning from using copying inks, typewriter ribbons and indelible pencils made with arsenical aniline dyes. Graffsky has described several very serious cases of chronic poisoning from handling colored chalk in one of the schools of Germany. A violet-colored crayon was found to contain over seven per-cent. arsenic. Clothing dyed with impure aniline colors has been the cause of many a sad case of illness. These cases have usually been caused by such wearing apparel as comes in direct contact with the skin, such as stockings, trousers, waists, etc. In Germany copper arsenite has been used for coloring tarlatan and several cases of serious poisoning have resulted therefrom. Two of the most striking cases of arsenical paralysis with which we are acquainted were due to green tarlatan ball gowns. Zinreck states that he found in twenty yards of this material used for a ball gown 300 gm. of Paris green.

Medicinal preparations have given rise to poisoning, either from overdosage or because of the presence of arsenic as an impurity in the substance administered, as, for example, in bismuth subnitrate and other bismuth preparations, sodium phosphate, glycerin, chloroform, phosphoric acid, sulphuric acid, etc. For the composition and dosage of arsenical medicines, see *Arsenic*, Vol. I., of REFERENCE HANDBOOK.

Industrial poisoning by arsenic is by no means rare, for in a large number of industries the workmen are exposed to compounds of this element in one form or another. In the following table will be found a list of trades or articles manufactured which are credited with cases of arsenicism, and a brief statement of the cause of the illness.

Name of Industry or Article Manufactured.	Causes of Poisoning.
Paints in which the basis is orpiment, copper arsenites, mineral blue, etc.	Arsine, arsenical dust.
White enamel glass, stained glass and certain other glasses.	Arsine, arsenical dust.
Copper, cobalt, nickel, zinc, tin.	Arsenic dust in air from roasting arsenical ores.
Copper refined in the wet way.	Arsine.
Hydrogen for balloons, limelights, when made from iron or zinc and an acid.	Arsine.
Phosphoric acid.	Arsenic trioxide.
Sulphur and allied industries.	Arsenical dust, arsine.
Arsenic and arsenical preparations.	Arsenical dust in mines, charging and emptying retorts, handling products.
Galvanized iron, tinned iron.	Arsine.
Zinc chloride.	Arsine.
Copperas (ferrous sulphate).	Arsine.
Aniline dyes by the arsenical method.	Arsenic acid, arsenous acid in dust, in air or on hands.
Artificial flowers, leaves, etc.	Arsenical pigments or dyes by contact, or in dust in air.
Stuffed animals, birds, preparation of natural history specimens.	Arsenic trioxide, arsenical soap and fluids absorbed by hands or in dust.
Bird shot (arsenic used to harden the lead).	Arsenical dust.
Aniline from nitrobenzene.	Arsine.
Indigo blue.	Arsine.
Embalming fluids.	Arsenic trioxide, arsenites of sodium, potassium calcium.
Preservation of wood.	Arsenical dust.
Wall papers, colored papers.	Arsenical dyes and pigments in dust or by handling.

Channels of Introduction.—Accidental poisonings are the result of swallowing the poisonous material, breathing arsine or arsenical dust, or occasionally absorption through wounds or through the sound skin. But in criminal cases every conceivable channel has been used, the usual mode of introduction being in food or drink. A number of cases are recorded in which the poison has been administered to the victims by enemas or vaginal douches. The legend that Ladislas, King of Naples, met his death in 1414 by arsenic introduced into the vagina of his mistress by a jealous courtier, and that Calpurneus murdered his wives by digital introduction of arsenic into the vagina are probably not mere myth and fiction, for we find several modern imitators of Calpurneus. In one instance the arsenical material was introduced by placing the poison under the prepuce, and introducing it into the vagina in this manner, so as to avoid all danger of detection. In another instance three wives were successively murdered by placing in the vagina a mixture of flour and arsenic trioxide. Experiments on animals have shown, beyond the possibility of a doubt, that death may result from arsenical poisoning through such an introduction of the poison into the body. A few cases are found in which arsenical vapors have been employed with criminal intent, as for example the vaporization of arsenic trioxide and the roasting of arsenical pyrites in a room.

Fatal Dose.—Brouardel's investigations have shown that the toxicity of arsenic varies according to: (1) The method of administration; (2) the kind and age of animal; (3) the nature of the food material present in the alimentary canal. Owing to the fact that some persons have, to a certain degree, a natural or acquired resistance to arsenic it is difficult arbitrarily to set any definite figure as representing a fatal dose. Moreover, when the stomach contains a large amount of fatty material a huge dose can apparently be ingested without fatal results. It is to be said in this connection that a very large dose is seldom as dangerous as one consisting of close to what may be said to be the normal fatal dose, for the reason that vomiting is apt to be immediate and the poison is removed at once without having undergone resorption. For As_2O_3 the toxic dose for man can be set as lying between 5 mgm. and 50 mgm. (0.07–0.77 grain), and the fatal dose 100–300 mgm. (1.54–4.63 grains). For Paris green the doses are probably somewhat higher than twice these quantities. The above figures refer to per-os administration. When the poison comes in direct contact with the blood, as for example through wounds, the abraded skin, or the direct introduction into the body by some sharp instrument, it is about ten times as active. Rouyer has attempted to calculate the toxic and fatal doses on the basis of the amount of poison resorbed rather than the total amount taken. According to his experiments and calculations 0.6 mgm. As_2O_3 resorbed per kilogram body weight will give rise to serious symptoms; 2.5 mgm. per kilogram may cause death in twenty-four to twenty-five hours, while 3 mgm. per kilogram will always cause death in about eight hours. It would seem that Rouyer's figures are probably too high, for they would require the resorption of about 200 mgm. to cause the death of a man of average weight. The actual dose to be ingested would therefore be considerably higher.

In the case of animals we find great variation in the intensity of the action of arsenical compounds, not only with respect to species, but also in different individuals of the same species. Von Gohier has seen a horse remain to all appearances in good health after a dose of 30 gm. of arsenic trioxide, while on the other hand 3 gm. has caused death. Not only do we have this variability of action on different individuals, but veterinarians are fairly well agreed that, particularly in the case of cattle and sheep, an animal may at one time stand a dose as high as 20–30 gm., while the same identical animal will suffer severe illness from 5 gm. at another time. The following table, while necessarily more or less arbitrary, can be taken as probably as nearly in accord with experimental data as is possible with our present knowledge.

	FATAL DOSE.	
	When taken internally.	When by wounds.
Horned cattle	10.0 to 30.0 gm.	2.0 gm.
Horses	10.0 to 25.0 gm.	2.0 gm.
Sheep, goats	5.0 to 15.0 gm.	.2 gm.
Swine	.5 to 1.0 gm.	.2 gm.
Dogs	.1 to .2 gm.	.02 gm.
Fowl	.1 to .15 gm.	.01 gm.
Pigeons	.05 to .1 gm.	.005 gm.

It will be seen from the above that sheep and goats are, per kilogram weight, remarkably resistant. A similar resistance is frequently met with in certain dogs.

Habitual Use, Tolerance, Arsenicophagia.—Aside from certain species of fungi and bacteria, arsenical compounds are toxic to all other forms of life. But by repeated small doses a certain immunity is at last acquired, after which enormous doses can be swallowed with impunity. This fact was known in most ancient times, for we are told that Mithridates (first century B.C.), who was well versed in the poison lore of his time, acquired immunity in this manner to protect himself against poisoners. By far the most striking cases of acquired tolerance are to be found among the mountaineers of Tyrol, Styria, Carinthia, the Punjab, and in some parts of the mountain ranges of South America. These mountaineers start taking arsenic, in the form of orpiment or the trioxide, from their youth; the men believing that it enables them to endure greater fatigue, wards off the mountain sickness and makes breathing easier; the women in order to improve their complexion, to acquire shining eyes, a rosy tint, and a well-rounded form. These arsenicophages seem to enjoy perfect health and reach an advanced old age. They exist, however, in a pseudo-normal state, for the suppression of the daily dose of arsenic leads to serious illness. The majority never reach a very high daily consumption of the drug, but instances are not lacking in which the amount taken daily reaches 300–400 mgm. We also have proof positive that certain individuals have taken this same amount at a single dose without suffering any inconvenience thereby. This tolerance and habit seem in many cases to be hereditary. A somewhat similar resistance is met with in patients who have been subjected to arsenical treatment with increasing dosage. After a time considerably over the maximum dose is tolerated. In Europe and in America certain waters are found containing arsenic. These waters have been long used by the inhabitants of the district, but no evil effects have been reported.

The administration of arsenic to horses by grooms in increasing doses has been practised for many years, especially in England, the object being to improve the animal's coat, aid the assimilation of food, and to give them a plump, well-rounded appearance. The arsenic is either mixed with the food or is tied in a tiny piece of cloth and attached to the bit. This latter procedure results in the production of a slight salivation and the appearance of white foam about the mouth, the animal holding its head erect and champing at the bit, conditions which are supposed to indicate a spirited animal. Horses subjected for any length of time to this treatment require a continuance of the daily dose, without which they rapidly lose flesh and condition.

There is as yet no satisfactory explanation for the acquired tolerance of arsenic. The theory that there is an abnormal rate of elimination by the kidneys is not well established, and is insufficient to account for all the facts.

SYMPTOMS. ACTION.—With the possible exception of the gaseous compounds all other arsenical substances may be said to have a like action on man. No matter, therefore, in what form arsenic is administered the symptoms observed will not differ to any appreciable extent. These symptoms can be grouped under four different heads. Those typical: (1) Of a mineral acid—acidismus. (2) Of a mineral salt—metal toxicosis. (3) Of action on the nervous system: (*a*) splanchnic paralysis, resulting in hyperæmia of all abdominal organs; (*b*) neuritis. (3) Of inflammation of the intestinal tract and of fatty degeneration, especially of the heart. The result of the ingestion of the poison may lead to either acute or chronic poisoning. In acute poisoning it is possible to distinguish three forms: A gastro-enteric or ordinary form, paralysis arsenicalis, and asphyxia arsenicalis.

Acute Poisoning.—Ordinary Form. Soon after swallowing the poison the victim complains of a disagreeable metallic taste in the mouth, of an annoying burning, itching, or tickling dryness of the throat, there being usually frequent spitting and more or less salivation. This is generally, but not always, followed by pain in the upper part of the alimentary canal which gradually passes downward, increasing in severity. In most cases in from one to two hours, rarely later, after swallowing the poison, nausea, vomiting, and purging set in. In the event of Paris green being taken, vomiting sets in at an earlier stage than is the case with other arsenical compounds. The vomited matter may be streaked with blood, or green if copper compounds are present. In a short time the stools which were at first colored with bile, become frequent and rice-water-like. Usually there is tenesmus. The patient finds more or less difficulty in swallowing, suffers from dizziness, headache, pains in the limbs, a burning unquenchable thirst, and often a distressing hiccough. The abdomen is distended and is painful on pressure, the secretion of urine is diminished, and there may even be anuria. The patient's voice becomes hoarse, features pale and haggard, eyes sunken, skin cold and dry. The pulse becomes slow and weak; respiration difficult and oppressed, and death usually takes place in fifteen to twenty-four hours, but often on the second day. The patient is ordinarily conscious to the last, but there may be coma, paralysis, or convulsions. If death does not occur before the second or third day, there is usually an apparent general improvement, save for the persistence of the dryness of the mouth and severe thirst. The temperature remains about normal or very little above. There is apt to be extensive erythema or an erysipelas or œdematic swelling which is most marked on the face and genitals, but there are patches more or less scattered over the body. There may be falling out of the hair. Blebs or pustules may appear on various parts of the body, or there may be circumscribed efflorescences. In many instances recovery is difficult and very protracted. Arsenical applications to the sensitive skin ordinarily give rise to severe dermatoses; as, for example, arsenical eczema of the legs and thighs from contact with trousers or stockings colored with arsenical aniline dyes. There may even be gangrene.

Arsenical paralysis is seen in both acute and chronic poisoning, but an extensive paralysis is rare. Seisser in the famous Würtemberg mass-poisoning observed only 1 case in 373. Alexander has collected the records of 55 cases of arsenical paralysis; of these 17 resulted from chronic arsenicism, while 38 were acute. In the great mass-poisoning in Great Britain in 1900, a very large proportion seem to have been troubled with paralytic symptoms. When arsenical paralysis results from acute poisoning it does not usually appear prior to the fourth day, or even the end of the first week. The normal termination of the seizure is the first half of the second week. The beginning of the trouble is marked by pain and paranæsthesia; soon there is numbness of the hands and feet, extending to the forearm and lower leg; very rarely is the paralysis of greater extent. Pain, which is seldom absent, may be very severe (anæsthesia dolorosa); it may be either constant or intermittent. The paranæsthesia has been variously designated by patients as a "sleepy," "furry," "itching," or "tingling" sensation. The hands and feet are cold, the tactile sense is disturbed as well as the temperature sense, cold water is mistaken for warm, while hot water is not recognized as such. As a rule loss of motility follows in a few days, but may also occur simultaneously with the paranæsthesia. In the majority of cases the patient cannot walk or stand for weeks, or even months, after the attack, but occasionally the effects soon disappear. The muscles first and chiefly affected are the extensors and abductors of the toes, later those of the fingers, and finally those of the lower and upper limbs. According to the investigations of Imbert-Gonebeyre the paralysis may be confined to the knees and elbows. Following the paralysis there is increasing muscular atrophy, which may reach an extraordinary degree of severity. Von Marik has described a case in which almost all the body muscles were affected.

Paralysis arsenicalis may be confused with tabes, alcohol neuritis, syringomyelitis, etc.

Asphyxia arsenicalis is a term given by several authorities to rare cases of exceptionally acute arsenic poisoning with unusually rapid death. In this form there is extraordinarily severe intestinal catarrh with vomiting, diarrhœa with rice-water stools, tenesmus, tonic convulsions first of the lower limbs, later of the upper limbs, cyanosis and death, with marked paralysis of the muscles of respiration in a few hours. This form of poisoning bears a striking resemblance to cholera asiatica of malignant type.

Chronic poisoning is seen most often in workmen in the metallurgical industries, in dye and paint works, among taxidermists, etc. A detailed list has already been given. Hill has also recorded a very unusual case, the alleged result of burning gas made from coal very high in arsenic.

According to Brouardel and Pouchet, who have made one of the most careful studies of arsenicism, there are four distinct phases in the progress of the disease. These phases correspond quite closely to the grouping given above under acute poisoning, but are more marked. The early stages of the disease can be characterized as protracted gastro-enteric catarrh. There are loss of appetite and vomiting of mucus and bile. Vomiting and pain may, however, be absent. The patient is apt to suffer from headache, faintness, irregularity of the bowels, depression, and loss of sleep. The breath is fetid, and the perspiration exhales an alliaceous odor like that of arsine. There is great emaciation. Fever and œdema may or may not appear. The urine is albuminous, contains hyaline cylinders, and substances reducing Fehling's solution. Sugar is rarely present. The urine contains arsenic, and on standing deposits magnesium-ammonium arsenate. A common accompanying symptom of much diagnostic value is obstinate conjunctivitis, together with redness and burning of the eyelids, and defective tear secretion. The throat and nasal passages are sometimes dry and irritated. The voice is hoarse. There may be slight cough, which, in cases arising from breathing arsenical dust, passes into more or less severe bronchitis. At other times the victims suffer from an influenza-like snuffle and the nasal secretions are flecked with blood. Many cases of arsenicism have been diagnosed as "grippe," "cold in the head," etc. The skin is far more severely affected than in acute poisoning. There is generally urticaria or an erythematous eruption, or desquamation. Sometimes papules or vesicles form on the breast, back, and face, while later pustules may appear in the arm pits, upon the scrotum, or in the vulva. Frequently the face takes on a dusky tint, and there is marked pigmentation of most of the exposed parts and the pressure areas of the body, or this pigmentation is confined to the knees, about the neck, and to the region of the stomach. The victim appears to be dirty. So dirt-like is this pigmentation that patients upon their admission to hospitals have been given several successive baths. The hair first turns gray, then falls. There may be growths on the nails; the latter may even be shed. Hyperkeratosis of the hands and feet of short duration is seen in not a few cases. Following the typical symptoms of cachexia and muscular atrophy there is wasting away of the muscles, especially of the lower limbs, though the arms may also be affected and the hands become claw-like. Icterus is neither constant nor characteristic, yet is frequently observed. It never reaches the intensity met with in poisoning by phosphorus. True paralysis arsenicalis seems to be of less frequence in chronic poisoning than in acute; but if it does appear its effects are of greater duration, lasting even a life-time. There are often hemianæsthesia and hemiplegia. According to the reports of cases of poisoning from arsenical beer, published in the *Lancet* in 1900–02, it would appear that a large percentage of the victims suffered from more or less marked paralysis, as shown by difficulty in walking, numbness, pricking, tickling, etc., of the lower limbs from the knees down, and from the elbows down, often accompanied by exquisite pain.

Mackensie has reported cases marked by paralysis of the vocal cords. Another peculiar form of paralysis has been studied by Charcot and Biett, and has received the designation anaphrodisia arsenicalis, because of the fact that the disease is characterized by a paralysis of the nerves of sexual sensation. Five typical cases are known. The physical diagnosis of chronic arsenical poisoning is very difficult. The most reliable method of reaching a decision consists in testing the urine for arsenic. This chemical diagnosis must never be omitted. The fatal period in chronic poisoning is too variable to permit of any statement.

Poisoning by arsenic may sometimes be confused with poisoning by phosphorus, antimony, ricinus, croton, abrus, robinia, podophyllum, etc.

Elimination of arsenic takes place chiefly by the kidneys; but there is reason to believe that in addition to the urine, the bile, milk, and perspiratory fluid play an important part, and that a certain portion of the poison is still further thrown out through the intestines. Arsenic can be detected in the urine in from two to eight hours after resorption, and is usually completely eliminated from the body, save from the bones, in from eight to twenty days. The normal period of elimination seems to be from twelve to fifteen days. This holds true only for acute poisoning, since in chronic poisoning, followed by recovery, the liver seems to retain arsenic for a long period; just how long is not known, but in animals it has been shown to be beyond forty days after the ingestion of arsenic ceased. Wood asserts that he has found arsenic eliminated eighty to ninety days after ingestion. On the other hand, Kunkle reports a case of poisoning by copper arsenite followed by death in seventeen hours, yet no arsenic could be detected in the liver, the stomach, or the intestines.

Saveri has shown that the arsenic eliminated by the urine is in the arsenous condition. Selmi has gone a step farther and has shown that part at least of the arsenic is eliminated in combination with organic matter as an arsenical organic compound, and that doubtless another portion of the arsenic is eliminated as arsine. The question of the elimination of arsenic through the milk is one of very great importance. In the light of experimental evidence and of cases collected, it is now possible to assert positively that an infant nursing at the breast may die of arsenical poisoning when its mother is undergoing arsenical treatment, or has swallowed some arsenical compound yet not in sufficient amount to give rise to illness of the mother; or, in case of a toxic dose having been ingested, there may be death of the infant before the appearance of symptoms of poisoning in the mother.

For information as to the localization of arsenic and its distribution in the body after death, the reader is referred to Vol. VI., p. 722, of the Reference Handbook.

Post-mortem Appearances.—In acute poisoning the findings are but slightly characteristic. In rare cases negative results will be obtained, but only when death has been unusually rapid, as for example in cases of arsenical asphyxia. No matter through what channel the poison has been introduced, the mucosa of the stomach and intestines will generally be found to be swollen, covered with bloody foam, more or less uniformly red, intensely inflamed, or hemorrhagic. In some cases there is ulceration, even necrosis. A few cases of perforation are known. Corrosion may take place in a few hours (five or six), and after ten hours may be very severe; this may not be confined to the stomach alone, but may be seen in the intestines. The small intestine is commonly more or less filled with colorless, watery, offensive contents, while the large intestine contains fæcal matter colored with bile. The liver, though apparently normal, shows on section marked fatty degeneration. Similar conditions obtain in the kidneys and heart. The blood shows no specially marked change, but its alkalinity is greatly decreased. In all but a few cases there is a remarkable preservation of the body with the internal organs fresh and of almost lifelike consistence, or there may be mummification. Either of these conditions existing in an exhumed unembalmed body should lead to a strong presumption of death by arsenic, but the practitioner must never lose sight of the fact that preservation and mummification are far from being constant or peculiar to this poison. In deaths following chronic poisoning the findings are quite uncertain. The most constant are atrophy of the muscles, a dusky skin often marked with blackish patches, alopecia, gastro-adenitis, and hepatic, renal, and cardiac steatosis.

The *mechanism* or action of arsenic compounds can be briefly summed up as follows: (1) Local cauterization; (2) vaso-motor paralysis of splanchnics; (3) degeneration of albumin of the body and disturbance of metabolism; (4) disturbance of activity of the central nervous system and of the skin; (5) paralysis of the heart.

Following the paralysis of the peripheral extremities of the splanchnic nerves there results great hyperæmia of the abdominal organs, giving rise to an appearance of inflammation. This condition extending to the mucosa becomes severe gastro-enteritis, explaining why it is that these lesions are seen, no matter what may have been the mode of entry of the poison. The disturbance of the metabolism leads to fatty degeneration of most of the internal organs, and especially of the glands. When this steatosis affects the walls of the blood-vessels, multiple hemorrhage results. As an immediate consequence of fatty degeneration of the heart muscles the ganglia become affected and cardiac paralysis results. The severe cerebral disturbances sometimes seen can be ascribed in part to the sinking of the blood pressure, and in part to degeneration of the ganglionic cells of the brain.

Normal Arsenic.—The question as to whether arsenic is a normal constituent of the body has been the subject of several investigations within the last few years. The weight of evidence seems to support the theory of Armand Gautier, that arsenic is always to be found in the healthy body at least in the thyroid, where it plays an important part, and in the hair, nails, bones, and mammary glands, and that this normal arsenic is eliminated chiefly by the skin and the milk. Before this theory can be accepted as proved more research is needed.

Antidotes. Treatment.—The most effective antidote with which we are now acquainted—freshly precipitated ferric hydrate—was first proposed by Bunsen in 1834. It depends for its efficacy upon the fact that it unites with arsenous acid, arsenites, or arsenates to form insoluble compounds. With arsenous acid or arsenites a basic ferric arsenite results, mixed with a variable proportion of basic ferrous arsenite, while with arsenates a basic ferric arsenate is formed. The ferric hydrate must be freshly prepared, since it soon loses the power to unite to form an insoluble compound. The official method of preparation is as follows: To ammonia water (U. S. P.), 110 c.c., add water 250 c.c.; to solution ferric sulphate (U. S. P.), 100 c.c., add water 1,000 c.c. Pour with constant stirring the solution of ferric sulphate into the ammonia water, pour the mixture on a muslin filter, squeeze, and add to the precipitate sufficient water to make about 250 gm. Of this final preparation administer to an adult two to four tablespoonfuls every ten minutes. The dose for a child is one dessertspoonful every ten minutes. Hydrated magnesium oxide, proposed by Bussy in 1846, is also of much value. Like the iron antidote it must be freshly prepared. One part of freshly burnt magnesium oxide is suspended in twenty parts of water. Of this preparation four to six tablespoonfuls may be administered every fifteen minutes. As in the case of iron, insoluble basic arsenites and arsenates result. In Europe the two above antidotes are combined, as, for example: To Liquor ferri sulph. oxydat. (P. G.) 100 gm., add water, 250 gm. To water, 250 gm., add magnesia usta, 15 gm. Mix the two solutions, shake well, and throw upon muslin.

Both the iron and magnesium compounds must be removed from the stomach as soon as possible, since the insolubilized arsenic may be again resorbed through the solvent action of the fluids of the body. A recommendable procedure is to wash out the stomach with water holding magnesium oxide in suspension; then administer the antidote. After a few minutes induce vomiting, or use the stomach pump. Repeat this process several times. Demulcent drinks should be promptly given to retard resorption—milk, albumen in water, flour and water, etc. Following the antidote, the treatment must be symptomatic. It must never be forgotten that during convalescence the diet must be watched with great care, and only bland articles given.

In the absence of the above-mentioned antidotes, ferric hydrate, prepared in any way, can be given, or the following may be employed with more or less success: saccharate of iron, acetate of iron, citrate of iron, dialyzed iron, powdered or reduced iron, milk of lime, sulphur, sulphide of iron, etc. The administration of alkalies must be carefully avoided.

Poisoning by Arsine is probably of greater frequency in the industries than is generally believed, though acute poisonings are quite rare. Arsine or arseniuretted hydrogen is a heavy colorless gas of peculiar fetid odor. Its specific gravity is about 2.7. It is but slightly soluble in water, and burns with a characteristic bluish-white flame. The pure gas is a frightfully active poison, only a whiff or two causing death. Of some twenty cases of acute poisoning on record, practically all have been the result of chemical laboratory accidents, but subacute and chronic poisonings are frequent in the industries where small amounts of arsine are breathed in the air of ill-ventilated work-rooms. Although the odor of arsine is characteristic and very penetrating, the gas may be present in the air of a room in sufficient amount to lead eventually to poisoning, and still not be detected by the sense of smell, or at least not noticed. Poisoning occurs chiefly in the preparation of hydrogen and the manufacture of balloons or toy balloons; in the coloring or bronzing of brass and other alloys; in the desilvering of lead and subsequent treatment of the silver zinc with acids; in the galvanizing and tinning of sheet iron; in the reduction of nitrobenzene, etc., in the aniline industry; in the manufacture of many salts; in fact, in all industries or operations where hydrogen is given off in reactions between compounds containing arsenic as an impurity. Besides these sources there is the further possibility of poisoning from wall papers in damp, ill-ventilated rooms through the formation of arsine by fungi and bacteria.

In strictly chronic poisoning the specific action of the poison manifests itself in anæmia or pernicious anæmia.

The effects of arsine on the system appear slowly. The victim shivers, complains of chills, and often of an indescribable feeling of sickness passing into great uneasiness and fear, resulting in exhaustion, weakness, and repeated fainting fits, during which the body is cyanotic, cold, and bathed in cold sweat. There is a blackness before the eyes and the pupils are dilated. There may or may not be nausea and vomiting. The pulse is somewhat accelerated but small and weak. Respiration is dyspnœic. The breath and mouth are fetid. After eight or ten hours, or even much later, the specific effects of the poison manifest themselves; the red blood corpuscles are destroyed and methæmoglobin is formed. All the urine passed is bloody, deep red, dark brown, or even black. There is sometimes anuria. Polycholia sets in and the skin becomes icteric or dark-colored. The stools are not watery as in arsenicism, but are colored dark with bile. The liver and spleen are swollen and painful on pressure. There are severe headache and a fear of death. Death occurs from œdema of the lungs or from paralysis of the heart. If death does not result the period of convalescence is generally very long. Spectroscopic examination of the blood for bands of methæmoglobin is of great value in diagnosis. These characteristic bands will also be noted after death, providing that an examination is promptly made.

The treatment of cases of arsine poisoning is difficult and unsatisfactory. Sodium bicarbonate should be administered to convert the methæmoglobin into alkaline methæmoglobin, which the body can readily change to oxyhæmoglobin. Transfusion of blood may often be imperative. The clogging of the canals of the kidneys has been successfully treated by injection of normal salt solution. The remaining treatment must be symptomatic. In the choice of stimulants to counteract the severe depression of the heart's action it should be remembered that alcohol is barred because of its action on the kidneys.

Clinical Tests.—For the rapid detection of arsenic in the urine, vomited matter, stools, etc., where much organic matter is present, there is nothing superior to the Reinsch method, *i.e.*, acidification with pure HCl and boiling with a tiny strip of pure copper foil or gauze. The stained copper should then be tested by heating in a glass tube in contact with air and the crystalline sublimate of As_2O_3 examined with a hand lens or microscope. For inorganic material the modified Gutzeit test will be found to be rapid and reliable. The gases evolved by the action of sulphuric or hydrochloric acid on zinc in the presence of a solution of the material to be tested are passed through cotton moistened with lead acetate (to hold back any hydrogen sulphide), and are tested either with filter paper moistened with mercuric chloride or with a dry crystal of silver nitrate. In the presence of arsenic the mercuric chloride spot turns brick-red, orange, or brown; the silver nitrate crystal first canary or lemon-yellow, then black.

Emile Monnin Chamot.

ASIATIC CHOLERA.—(Synonyms: Epidemic cholera, Cholera asphyxia, Algid cholera, Malignant cholera, Cholera spasmodica, Pestilential cholera, Pestilential asphyxia, Oriental cholera, Choleric pestilence, Indian cholera, Ganglionitis peripherica et medullaris, Trisplanchnia, Hyperanthraxis, Morbus oryzeus [because supposed by Tytler to be due to damaged rice], Troussegalant, Cholera gravior, Vishucki or Vishuchiki [by Hindoo physicians], Haouwa [tornado] in Bagdad.) (For a wider discussion of terminology, see Macpherson, "Annals of Cholera," chapter ii., ed. 1884.)

The derivation of the word cholera is usually from *χολὴ ῥεῶ* (flow of bile), or *χολὰς ῥεῶ* (intestinal flux), but the correct one is probably that given by Jobard, of Brussels (*Gaz. Méd. de Paris*, 1832, p. 389), who considers the term to be made up from two Hebrew words, choli-ra (or morbus malus).

Asiatic, or epidemic, cholera is an acute infectious disease that is endemic in certain parts of India, and that has during the last century advanced out of that country to other parts of the world, where, in its epidemic form, it has produced great loss of life. It is characterized by its great fatality among the communities to which it may be transported, by the apparent ease with which it has been carried from place to place, and by its invariably following the lines of travel in its march from one place to another. It is distinctly a disease of the gastro-intestinal tract, produced, primarily, by a micro-organism and attended with secondary symptoms, due to the absorption of toxic principles elaborated during the development of this micro-organism.

There is only a difference of degree between cholera, choleraic diarrhœa, and cholerine—the disease is the same in all these forms provided that they are accompanied by the activity of the spirillum of Koch. So far as true cholera and cholera nostras are concerned, there is a very great similarity, or rather there may be, between the clinical symptoms of the two diseases, but the differentiation may be easily made by the isolation of the specific spirillum of the former. The same thing is true in regard to the differentiation of true cholera from an attack of indigestion, which, if severe enough, may take on many of the characteristics of true cholera. Cholera nostras is a seasonal disease and is not transportable, and it has been known for ages. True cholera made its first advance out of India in 1817, and since that time has been seen periodically in Europe. In all cases it has followed the line of travel, and has never been seen to be distributed in any other way. Therefore true cholera never makes its appearance except after other cases have been seen that might excite suspicion, while cholera nostras appears only in hot weather, in sporadic cases, and dies out if the weather becomes cooler.

The period of cyanotic chills, although one of the most striking in both diseases, gives no special indications for differential diagnosis, for the same thing is seen as an accompaniment of many other diseases, as acute catarrhal diarrhœas, acute poisonings, etc. The prodromic period exists in cholera nostras practically always, but not nearly always in true cholera.

The period of reaction is of importance in differential diagnosis. In cholera nostras it is usually benign—if the patient escapes the violence of the first attack, convalescence is as a rule easy and rapid; with true cholera, on the contrary, convalescence is exceedingly dangerous—full of pitfalls, and may terminate fatally at any time.

Mention of the disease is made in Sanscrit and Chinese writings. It is spoken of by Hippocrates (Epidemics), and successively by Aretæus, Celsus, Galen, Caelius Aurelianus, Aëtius, Paulus Æginatus, and Alexander de Tralles. All of these writers, with many others, refer to affections resembling the cholera, but it is not until the seventeenth and eighteenth centuries that we find descriptions of the *epidemic* disease. Genuine epidemics, analogous to cholera, are described by Rivière, who made his observations at Nîmes in 1564, and by Zacutus Lusitanus, who saw several in different parts of Europe in 1600. The most remarkable accounts by authors of this epoch are those of Willis ("Opera Gen.," 1680, t. xi., p. 74), describing epidemics in London, in 1670, of what he called "dysenterica aquosa epidemica," of Thomas Sydenham, in 1669–76 ("Oper. Med.," Geneva, 1723, pp. 106 and 184), and of Torti ("Therap. Spec.," liv. iii., cap. ii., and liv. iv., cap. j.). Bontius ("De Medic. Indorum.," Lugd. Batav., 1642, p. 136), Delon ("Voyage aux Indes Orient.," Amsterdam, 1684), and Thevenot ("Voyage aux Indes Orientales," Paris, 1689, tom. iii.) observed and described epidemic cholera in India. In 1761, Donald Monro ("An Account of the Diseases in the British Military Hospital in Germany," London, 1764, p. 97) saw an epidemic of cholera in Westphalia; as did Agton Douglass and Bisset, in 1768, in the north of England and in Scotland. Harlem ("Die Indische Cholera"

1831, t. i., s. 144) quotes many dissertations upon the disease, but it is not until the last century that we have a clear account of the transportation of the disease from place to place. From 1817 it seemed to take on a new power of travelling, and owing to this spread the opportunities for its study have vastly increased. The new methods of intercourse and commerce were probably responsible for the appearance of the disease in Europe—not any new property which it developed.

A study of the history of the epidemics that have occurred outside of India will easily demonstrate the facts in regard to the ways by which the disease is transported from place to place.

History of Epidemics of Cholera and Their Lessons.—The dispute is active as to whether true cholera existed in India before its appearance outside of its limits in 1817, but the probabilities are all in favor of its having done so, epidemics of considerable proportions being reported in the eighteenth century; the especial point that seems to be changed in its nature being that it then seemed to take on the property of migration. Whether this was in reality a new property, or whether, as is much more probable, it was simply brought to the notice of Europeans by their being first attacked by it, is an unsettled question. There is no doubt, however, of the very great influence exerted upon its spread by the great pilgrimages to the various shrines of India; nor is there any doubt that the sole home of true cholera—the one place where it is present all the year in an endemic form—is the delta of the Ganges. There are also certain places in India, Indo-China, China and Japan in which it seems to be present nearly all the time, but it certainly is not endemic in Persia, on the borders of the Caspian Sea, nor in Mecca.

From this one place in which it is endemic, cholera has always been transported to Europe in the steps of the traveller and along the routes of commerce; neither wind, moisture, electricity, nor any of the forces of nature have taken any active part in the actual transportation of the disease, although unfavorable climatic and hygienic conditions, of course, may play a favoring part in the development of the disease, after the arrival of its cause.

Epidemics of Cholera.—Cholera has made five appearances in Europe—in 1830, in 1846, in 1865, in 1884, and in 1892. Each one of these appearances was a great epidemic.

There had been also, in 1823, in Astrachan, a small epidemic of cholera, important because it traced the route that the succeeding invasions would follow. Leaving Persia, where it prevailed in 1822, cholera invaded the southern provinces of Persia, forming the southern shore of the Caspian Sea. After some ravages, it became quiescent during the winter of 1822, to reappear in April, 1823, at Recht. From this city, following the western shore of the Caspian Sea, it crossed the Russian frontier in June, at the little town of Astara. From Astara it reached Lenkoran on the 29th of June. On the 11th of September it was seen at Bakou, and on the 22d at Astrachan, where it soon disappeared.

The First Epidemic.—The epidemic of 1830 had the same origin. Ghilan and Mazanderan, the two Persian provinces before invaded, were attacked in 1829. The disease was quiescent during the winter, but appeared in the spring in Ghilan and in the little port of Enselli, situated several hours' journey from Recht. As in 1822, the cholera followed the western border of the Caspian Sea, and snowed itself about the middle of June, 1830, at Salian. Taking here two different directions, on the one side it appeared at Bakou, Kouba, and Derbent, and invaded Astrachan; on the other, following the whole valley of the Koura, it advanced toward Tiflis, passing by Elizabethpol, and spreading throughout the whole of the Caucasus. In this way it reached successively the neighboring regions of Astrachan, and advanced up the Volga. On the 4th of August it was at Saratow, thence extending into Russia, and reached the other European States.

This epidemic, by certain extremely interesting peculiarities, demonstrated from the very first the transportability of cholera.

The Second Epidemic.—In 1846, after having reached Salian by a course identical with the preceding, cholera was seen on November 8th in the city of Chemacka, a short distance from Salian. It was in Bakou and at Derbent in December. Forgotten during the winter, it appeared in April, 1847, in the districts of Derbent and of Kouba, and at Tamir-Khan-Choury. From thence it was transported by sick soldiers to the mineral waters of Kisliar. The disease was disseminated among the Calmucks scattered over the steppes near the Volga.

On July 15th it appeared at Astrachan, and advanced at the same time toward Tiflis. From Tiflis it reached Koutais, and was soon carried to Trebizond.

North of Tiflis, the cholera followed the great military road that crosses the Caucasus at the height of seven thousand feet, and toward the end of July it existed at Stavaropol, on the other slope. (It is to be observed that before reaching Tiflis, the cholera entered Persia by the great routes of travel that pass from Bakou, by Erivan, Natchichievan, Djoufa, Ordoubaz, and on toward Tauris. On the one side it attacked the region of the Black Sea, and invaded all its ports; on the other, it passed through Russia, Germany, France, and Italy.)

A striking thing about these epidemics, aside from the exact places that they attack, is their progress by successive stages—a form of advance that is always the same, and which is a trait common to all the epidemics of cholera that have followed the land route. This second epidemic persisted until 1855.

The Third Epidemic.—The great epidemic of 1865 was the first one appearing by the sea route. It demonstrated that the danger is not localized on the Caspian Sea, but that it is also present on the shore of the Red Sea. Its appearance by this route upset all the doctrines that had been held until that time, and the panic that it produced in Europe resulted in the first conference at Constantinople. It is interesting to follow in some of its phases the course of this epidemic, because its influence has been great. It started from Mecca, having been brought into that city by ships coming from India filled with pilgrims. Toward the end of April it broke out in Mecca and at Medina. The mortality increased very greatly during the three feast days at Arafat. More than thirty thousand of the pilgrims died of cholera, and the progress of the disease showed that *everywhere it accompanied these pilgrims.* Egypt, by reason of its proximity to Mecca, was the first country attacked.

From May 19th to June 10th ten steamers landed from twelve to fifteen thousand pilgrims at Suez. By false declarations from the captains they were passed at Suez, although the *Sydney*, an English steamer, had lost a number of cases during the voyage. The first steamer, landing May 19th at Suez, had thrown its dead into the sea. On the 21st, cases appeared at Suez, and among the number were the captain of the vessel and his wife.

June 2d, the first case appeared at Alexandria, and in two months cholera had four thousand victims in Alexandria, and in Egypt, in less than three months, it produced the death of more than sixty thousand individuals The foreign population emigrated *en masse*, and carried with them throughout the entire world the germs of the disease. Europeans and Levantines, to the number of from thirty to thirty-five thousand, started for all the ports of the Mediterranean, and cholera developed at Constantinople, at Smyrna, at Beyrout, in Mesopotamia, and at Odessa on the Black Sea, and was carried to New York and Guadaloupe by steamers, *appearing in the port at the same time that the steamer landed its passengers.*

Its importation into New York was as follows: The *Atlanta*, an English ship, left London on October 10th with a cargo of merchandise and forty passengers. The sanitary condition of London was at that time excellent. Reaching Havre on the 11th, where it remained one day only, it embarked five hundred and sixty-four new passengers, mostly Swiss, who had all passed through Paris, where, with certain exceptions, they had remained at least a short time, and where at the same time cholera was raging with great intensity. Two German families had stayed in Paris at the Hotel of La Ville de New York, and five days at the hotels of the Weissen-Lamm and Huitgarderhof. Some emigrants that had arrived several days before in these last hotels had fallen suddenly ill. The steamer sailed on the 12th, and on the next day there was a death from cholera of a child in the family coming from the Weissen-Lamm Hotel. Five other deaths followed on the 14th, the 16th, the 18th, the 19th, and the 22d, in the family that had stayed at the Hultgarderhof.

On the arrival of the *Atlanta* the surgeon declared 60 cases of cholera, and 15 deaths during the voyage. Two deaths occurred in port, and of the 142 patients sent to the Marine Hospital from November 6th to 19th, 6 died, which makes a total of 23 deaths. The *Atlanta* was immediately isolated in the lower bay, and after ten days of quarantine all the sick were removed, and, thanks to these measures, New York was preserved.

There were also importations in 1866 by the steamers *Virginia* and *England*.

The epidemic of 1865 ceased in 1874, and there was no other case seen in Europe until 1884, although there were interesting manifestations in other countries and on the sea—interesting from the point of view of the transportability of the disease.

The Fourth Epidemic.—The epidemic in Egypt in 1883 was no surprise to those who knew the sanitary condition of the country. Cholera appeared at Damietta toward June 19th or 20th, possibly a little earlier, and its explosion at this time is ascribed, certainly by the French, to the suppression of all sanitary precautions, including quarantine, by authority of the British Government. This epidemic at Damietta increased for about fifteen days, remained stationary for about five or six days, and then diminished just as speedily. It was almost extinct a month after its appearance, having claimed from two thousand to twenty-five hundred victims. The spread of the disease throughout Egypt was manifest and rapid. (An interesting account of how this epidemic reached Damietta is given in Proust's work on the "Defence of Europe against Cholera," Paris, 1892, p. 7.)

Cholera had not yet died out in Egypt, before the news came that it had broken out among the pilgrims to Mecca, and there has been much discussion as to the origin of this epidemic.

In 1884 a number of vessels left the extreme East, and had cases of cholera on board during their voyage; but, by reason of the precautions taken, Egypt and Europe escaped the danger at this time.

The first case of cholera seen at Toulon occurred on June 13th, on the ship *Montebello*; a second case on June 14th; a third on the 18th, on the *Jupiter*, near the *Montebello*; a fourth, also on the 18th, on the *Montebello*; a fifth, June 20th, on the *Alexander*, which was also placed near the *Jupiter* and the *Montebello*. After the 21st the disease spread through different quarters of the city, and it is thus shown that it did not make its appearance at Toulon in the city, but just outside.

Its importation into Marseilles occurred by the appearance of the first case on June 27th, in a young man, who had three days before come from Toulon. The next case, which occurred on June 28th, was that of a man who lived in the same neighborhood; and from this time onward the disease continued to spread.

In Paris there appeared two cases on the 13th or 14th of July, but the epidemic did not really begin until the 4th of November.

In Brittany the first case was not observed until September 20th, at Concarneau. Other ports were successively invaded.

Algeria was attacked in 1884, and there was a slight recurrence in Algeria and in Tunis in 1885.

Cholera was brought to Italy in 1884 by the Italian workmen, who, to the number of more than eight thousand, returned to their country after the extension of the cholera to Toulon and Marseilles. The province of Cuneo, in Piedmont, was the first one attacked, on June 27th, and the disease spread successively to different parts of Italy, to Genoa, Naples, Venice, Sicily, and so on.

It appeared in Spain, in the month of August, in the province of Alicante, and ceased toward the middle of October, reappearing in the middle of February, in the district of Gandia, raging through the month of June to the month of December, 1885, and producing a considerable mortality. It is remarkable that it attacked especially the small towns more than the large cities. The Commune of Aldea de San Miguel, with only five hundred inhabitants, lost more than half of them in thirty-six days.

Cholera also appeared on the Adriatic shores of Croatia, at the end of 1885, and in 1886 on many points of the Austro-Hungarian shore in Istria and in Dalmatia.

The comparison of the mortality in France, Italy, and Spain is interesting. In France and Algeria together there were 13,000 deaths in a population of 39,000,000—1 in 3,000 inhabitants. In Italy there were 35,000 deaths in 26,000,000, that is to say, 1 death in 600 inhabitants. In Spain there were 180,000 deaths, among 17,000,000 inhabitants, that is to say, 1 death in 100 inhabitants. So it appears that Italy was attacked five times more severely by the epidemic than France, and Spain six times more severely than Italy, and thirty to forty times more severely than France.

Much has been said about the immunity of Portugal during the epidemic of 1884 and 1885 in Spain. Many reasons can be brought forward for this, viz., the slight tendency of the Spaniards to take refuge in Portugal, the geographical conditions, and finally, the prophylactic measures taken at the frontier.

In spite of the imperfect quarantine and incoherent measures prescribed by the governments of South America against the vessels coming from Europe, a ship from Genoa, the *Perseo*, carried cholera to Buenos Ayres, and the disease spread into the Argentine Republic, Uruguay, and Chili.

From 1884 to 1886, a period of three years, more than twenty vessels coming from the extreme Orient to Europe, on passing through the Red Sea and the Suez Canal, had, either at the moment of their departure or during the voyage, cases of cholera.

The Cholera of 1889, 1890, 1891, *and* 1892 (*the fifth epidemic*).—In 1890 cholera appeared in Irak-Arabi, in Mesopotamia, in Persia, and in Syria, where it had not been seen for almost twenty years. It had been imported into the region bordering on the Red Sea and into Mecca, where it had not been since 1883, and it was observed in Spain, where it had been extinct since 1885.

In summing up what we know of the origin of cholera in Irak-Arabi and in Mesopotamia in 1889 and 1890, the following must be our conclusions:

It is very difficult to admit that the cholera of Irak-Arabi can be attributed to the revival of the old epidemic of 1871, and if this hypothesis be excluded, we are obliged to accept the idea of importation, and it is only possible to think of one portal of entrance, the Persian Gulf, and one source in India, namely Bombay and its environs.

We know from other sources that during and before the appearance of cholera in Irak-Arabi the mortality of this disease in Bombay and its environs reached the enormous number of more than six hundred deaths a week. The condition of the vessels of the British India Company, that alone regularly frequent the Persian Gulf, bring passengers there, and frequently bring pilgrims from India, has been, to say the least, suspicious. Everything points therefore to the conclusion which bears every appearance of truth that the cholera penetrated into Irak-Arabi through Chat-el-Arab. The importation was performed in this way much more probably than by any other means.

In regard to the epidemic of 1890–91 in Hedjaz, Proust offered to the Committee of Hygiene the following conclusions which were accepted: (1) The cholera of Cameran was imported by an English vessel coming from India; (2) the cholera of Hedjaz appears to have been brought by the sea route; (3) the pilgrimage to Mecca is a constant menace to the health of Europe; (4) the measures prescribed for the government of the pilgrims to Mecca have not prevented the cholera from developing, and it is therefore necessary to perfect these measures; (5) the prophylactic measures prescribed by the Alexandrian Conference at the time of the return of the pilgrims, have this year prevented the disease from gaining a foothold in Egypt and in Europe. There is reason, therefore, for continuing this conference and for giving it more authority and making it in reality international. There is also reason for increasing the means for isolation and disinfection on the Red Sea.

The epidemic which appeared in Spain in the month of May, 1890, and lasted until the end of November, gave rise to much discussion in regard to its origin, a discussion that reached no final conclusion.

In 1890 cholera also appeared in Japan, beginning in June and lasting throughout the year. Over 46,000 cases were reported. The epidemic of 1892 appeared first in Southern Russia and thence spread to isolated parts in the north of Europe, notably Hamburg, where it continued, with declining severity, into 1893 and 1894.

In September, 1892, 10 cases, with 8 deaths, occurred in New York, being imported from Hamburg, or probably derived from such imported cases, and 73 cases, with 43 deaths, occurred in the harbor, together with 56 suspicious cases of disease thought to be cholera. In 1893, 23 cases, 4 fatal, occurred in the harbor, and one death, verified by bacteriological examination, took place in Jersey City, where there were also 6 deaths following a disease clinically diagnosticated as cholera. Since then no cases have occurred in this country.

In 1895 there were serious epidemics in China and Japan, over 12,000 cases, with over 8,000 deaths, being reported from the latter country.

In 1896 cholera appeared in Russia, Turkey, Egypt, and a few cases in Austria. During the years from 1897 to 1901, inclusive, cholera does not appear to have spread beyond the regions where it is endemic, except a few cases imported from those places.

In 1902 cholera assumed epidemic form in Mecca, Turkey, Russia, Japan, and China. There were also a few cases in Egypt and other southern Mediterranean countries. In the Philippines, between March 20th and the end of October, over 4,200 cases, with more than 3,300 deaths, occurred in Manila, and in the provinces outside of that city over 102,000 cases, with between 66,000 and 67,000 deaths. Since that time, and into 1903, cases of cholera have occurred in these islands. The first case came from Hong-Kong.

Transportability and Means by which the Disease is Transported.—The transportability of the disease is demonstrated by, first, the facts in regard to its propagation after it has been imported; second, by the efficacy of certain measures of prevention; third, by the general march of epidemics of cholera; and fourth, by the development of epidemics in the infected localities.

1. *Propagation.*—Brochard, in "Du Mode de Propagation du Cholera," Paris, 1861, reports a very large number of observations favoring the idea of the transportability of cholera, and the number of instances proving this is so great that they need only to be spoken of to be accepted.

An illustration may be taken from the article by Huette, in the *Arch. Gén. de Méd.*, 5th series, vol. vi., p. 571.

In speaking of cholera in Chatillon, he says that the first case was observed in the Faubourg du Puirault, in a workman, thirty-five years old, who was attacked immediately after his return from Oussoi, where he had gone to take care of his parents who were sick with the disease. His neighbors were very soon attacked, and the epidemic invaded the entire Faubourg du Puirault, where it remained concentrated for some little time. Finally the inhabitants, frightened by the disease, scattered through Chatillon, and the cholera appeared indiscriminately throughout the city. The instance is interesting, because while the inhabitants remained in the Faubourg du Puirault, the disease stayed there, whereas, as soon as they scattered, it spread with them throughout Chatillon.

Another instance, interesting as an example of the transmission of the disease by clothing, is given by the same authority, in speaking of the Commune of Oussoi. Madame Bresson, of the hamlet of Moulineuf, near Oussoi, a precinct free from cholera, received a boarder from Paris, June 27th, who on the next day showed the first symptoms of cholera, and died on July 3d. Some days after, a child of this woman was attacked and died on July 13th. On the same day Madame Bresson herself was taken sick, and died on the 17th, after having been taken care of by two neighbors named Sahan and Moret, who died, one on the 16th and the other on the 24th. The husband of Madame Bresson died on July 26th. Madame Burette, who lived in the extreme end of the hamlet, washed the linen of the two women, Sahan and Moret, and was attacked with cholera. In this way, an epidemic was started that carried off eighteen persons in a very short time. Before the arrival of the person from Paris no case had been observed in this hamlet, that had been spared by the cholera both in 1852 and in 1849. Dr. Huette calls attention to the distribution of this hamlet of Moulineuf, which is composed of ten little collections of houses, separated by great distances. No cases of cholera were observed excepting in three of these collections of houses—first, that occupied by the Bresson and Sahan families; second, that occupied by the Moret family; and third, that occupied by the Burette family. The third collection of houses was situated at the extremity of the hamlet. No case of the disease was observed in the other houses, of which the inhabitants had had no connection with these three families.

Proust (*loc. cit.*, p. 165) quotes an occurrence illustrating another series of facts.

In 1854 the French army was collected at Varna, a short distance from the English army. Some detachments remained at Gallipoli, the original place of debarkation. There were, besides, a small Anglo-French force of occupation in the Piræus, and also some detachments at Constantinople. The armies were reinforced practically every day by new arrivals. The sanitary condition was satisfactory in all respects. On July 5th the packet *Alexandre* arrived at Constantinople, having left Marseilles on June 26th with five hundred men of the Fifth Regiment of Light Infantry, coming from Montpellier, and having passed through Avignon, where cholera was raging. It appeared on board, and three men died during the voyage to the Dardanelles. Four cholera patients were landed at the Piræus, where the cholera broke out immediately, and made great ravages. The troops were disembarked at Gallipoli, where two new cases of cholera were immediately sent to the hospital, and the ship, having only a few passengers on board, sailed for Constantinople, where a quarantine was imposed on it. On the other hand, it appeared that previous vessels sailing from Marseilles had already suffered from cholera, and that one of them had landed a patient in the military hospital at Constantinople. On July 15th, after new arrivals of cholera patients, the disease spread at Gallipoli, and there appeared in the military hospital of Constantinople a choleraic focus. Fauvel, struck by the danger, proposed, and had adopted by the Council of Health at Constantinople, a momentary interruption of the communication between Gallipoli and Varna. The measures prescribed were not executed, and in spite of the insistence of Fauvel before the Marshal de Saint Arnaud, many ships sailing from Gallipoli passed the Bosphorus, and went directly to Varna, where free pratique was accorded them. Cholera then broke out in the army among the newly arrived soldiers and in the hospital. On August 5th the epidemic was violent at Varna, especially among the troops sent into the Dobrudscha. The English army was invaded, having the epidemic on board the fleet. In the Crimea, the epidemic, helped on by the arrival of the fresh troops, continued until 1856.

The importation of cholera into Constantinople in 1865 equally deserves to be spoken of. Constantinople was in an excellent sanitary condition when the frigate *Moukbiri-Sourour* arrived from Alexandria, on June 28th, 1865. She had passed more than five days on the voyage, and therefore, in accordance with the rule that then held, free pratique was granted her, the surgeon having declared that there had been no illness during the voyage; but this declaration was false. The evening of June 28th there were landed from this frigate twelve sick persons, of whom one was attacked with cholera, who died during the night, and eleven were affected with cholerine. It was learned on the next day that during the journey from the Dardanelles to Constantinople two choleraic bodies had been thrown into the sea. On June 30th nine other cases were landed. The ship was sent into quarantine at the mouth of the Black Sea. The patients were transported to the Marine Hospital, near the arsenal, and here one special circumstance should be noted. The road that went from the landing to the hospital being opposite, it was necessary to carry the sick past the barracks occupied by military workmen in the arsenal, and the first indigenous cases of cholera occurred among these workmen, and on board a corvette that was near their barracks. On July 3d one of these military workers was received at the hospital with a choleraic diarrhœa, and on the 5th presented all the symptoms of cholera. That same day a new case was furnished by the workmen, and another on the corvette spoken of above. The barracks were then vacated, and the workmen were placed in tents on the heights of Okmeidan; nevertheless, the disease continued to rage among them, and among the ships collected before the arsenal, and it attacked on the one hand the guard in the interior of this establishment, and on the other the workmen at the Ministry of Marine, situated very near the barracks of the military workmen. On July 8th two cases occurred outside the arsenal, and from July 10th the epidemic commenced to invade the quarter of Kassin-Pacha, near the arsenal, and inhabited by the workmen of whom we have spoken. It then propagated itself throughout the city.

One more instance of the importation of cholera may be given, as illustrating that a single case, carried a great distance by rail, may give rise to an epidemic.

Toward the end of the month of August, in 1865, cholera suddenly broke out at Altenburg, in Saxony, in the centre of Germany. The first case was that of Lady E——, who had left Odessa on August 16th, and had arrived at Altenburg on the 24th, without having stopped on the journey. She travelled with a child of twenty-one months old, who was affected with diarrhœa. She went to her brother's, and sent for a physician to see her child, whose diarrhœa had become very severe. This woman, who was meanwhile well, said that at her departure from Odessa there had not been in that city any disease; but this was an error, for some cases of cholera imported from Constantinople were already in the hospital in the lazaret, and, the day after the departure of this lady, cholera appeared at Odessa. She said also, that having embarked to go up the Danube, everybody appeared to her to be well on board, although the vessel had passed by certain localities where cholera was raging; however that may be, three days after her arrival at Altenburg, on August 27th, and the very same day that the physician had visited her child, this lady fell ill, and the next day the physician recognized all the symptoms of Asiatic cholera. She died on the 29th. On the same day, in the same house, her sister-in-law was attacked, and died on the 30th. The child died on the 31st. From this house the cholera spread into the city and suburbs. The family of a workman, who died on September 13th at Altenburg, carried the disease to Werdeau, and the house occupied by this family was the point of departure of another epidemic that carried off two per cent. of the entire population of the city.

2. *The Transportability of Cholera is Confirmed by the Results of Restrictive Measures.*—We see always that a rigorous sequestration and a rigorous interruption of communication by land or sea, if that be possible, result in preserving certain places or certain countries, and in these facts is a powerful argument against any idea of the transmission of cholera through the air.

In 1867 Messina and the whole of Sicily were entirely free from cholera, and yet vessels coming from infected countries daily passed through the narrow Strait of Messina. And again, during the epidemic of 1856 at Constantinople, the scholars of the Military School, to the number of five hundred, were rigorously sequestrated in the establishment, and escaped the cholera that was raging in the neighborhood; and events that occurred at the lazaret of Fort Genoa, in Algeria, in 1884, demonstrated also the efficacy of isolation in order to prevent the transportation of the disease to the neighboring cities.

3. *Transportability as Shown by the General Progress of Epidemics of Cholera.*—If we look at epidemics as a whole, we see that they always follow the course of human currents of travel. It is in the East, or in the countries bordering upon Europe, that we can best follow the development of this law, because in such places the routes are less frequented, and the demonstration is more striking. In order to pass from Persia into Russia in any way except by the great line of travel passing through Erzeroum, Tauris, and Natchischevan, there are only two ways—that over the Caspian Sea, and the land route that follows the western shore of this sea. Both of these routes pass by Recht, Astara, and Lenkoran, and end both of them at Bakou, and in the same way cholera, in the epidemics of 1823, 1830, and 1846, always and invariably passed through Recht, Astara, Lenkoran, and Bakou. At the latter city the land route splits on the north. It continues to follow the western border of the Caspian Sea, and passes by Derbent, and reaches Astrachan exactly as does the sea route, and we have seen cholera at every one of its appearances, in 1823, 1830, and 1846, travel over this same line, passing by Bakou, Derbent, and Astrachan. In 1823 it stopped at Astrachan, while during 1830 and 1846 Astrachan was only one of the steps of its invading march.

The second line of travel passes over the Caucasus. It leaves Bakou, passes by Tiflis, and follows the Caspian Sea to the Black Sea. The point of departure from the Caspian Sea is Bakou. The point of arrival on the Black Sea is Poti, or Trebizond. The epidemics of 1830 and 1846 divided, following both of the two routes that have been spoken of. One current followed the border of the Caspian Sea, another crossed the Caucasus.

This progress of cholera, always following the same lines, is a striking illustration of the law formulated. It always follows the human currents, in the steps of the traveller. It is imported by man alone, and precisely the same point is shown if we follow the successive steps of the epidemics that have travelled by the sea route.

As an illustration, the epidemic of 1854 in the Crimea was due to vessels coming from Marseilles, and carrying troops from an infected country. Cholera appeared successively at every one of the points where these vessels touched. They landed at Messina, and Sicily was invaded. They touched at the Piræus, and Greece was attacked. They stopped at Gallipoli, and cholera appeared at Gallipoli. Constant communication was being held between Gallipoli and the Dardanelles, Constantinople, and Varna. Cholera developed at all three places. The same was shown in the progress of the epidemic of 1865. It must not be supposed, however, that the assertion is made that cholera took the special direction from east to west; on the contrary, it radiated from India in all directions—north, south, east, and west—according to the ease and number of the means of communication.

4. *Transportability as Indicated by the Evolution of Epidemics in Infected Localities.*—Many examples of this may be quoted, among which are the following:

In Constantinople it is possible to trace out the successive extension of the disease up to the time of its general diffusion. At Constantinople it manifested itself first at the arsenal, where it had been carried by the sick who were landed from the ship *Moukbiri-Sourour*. From the arsenal it reached the neighboring quarter of Kassin-Pacha, and then a few cases appeared in different parts of the city, for the most part of persons who had fled from the quarter first attacked. Up to July 16th the total of the deaths from cholera in the entire city, except those at the Marine Hospital, reached one hundred and thirty, when suddenly it was learned that the disease had broken out with violence at Eini-Keni, a village situated on the Bosphorus, twelve or fifteen kilometres from the quarter where the epidemic had begun. It was established that the first case of cholera had appeared on July 11th, in a Turkish café, in a workman coming from Kassin-Pacha; that on the next day many of the individuals who frequented this café fell ill, and two died; that during the following days the disease was propagated in the quarter until the 16th, when, after the occurrence of several deaths among prominent families, a panic seized the whole population of the village, who fled in all directions. Mussulmans, Greeks, Armenians, and Jews fled into other villages and other quarters of the city which were then unaffected, but in which the cholera speedily made its appearance. The Jews in particular, who had been the most seriously attacked, and who carried with them their soiled clothing and their dead, became the special propagating agents of the disease. At Koustoundjouc, at Kas-Keni, and at Balata, the epidemic broke out immediately after the arrival of these fugitives. From this moment dates the generalization of the epidemic. It is not necessary to add other examples. The same thing is shown in the history of every local epidemic that has been intelligently traced.

It has been opposed to this idea of the transportability of cholera that sometimes a restricted intercourse has failed to arrest the progress of the disease; but in all these cases the measures were either tardily employed or applied without scientific rule. Others have spoken of the immunity of countries which had not protected themselves by any sanitary measures. The answer to this is the question, whether cholera, although it is a disease capable of spreading by infection, must, therefore, be possessed of a method of forcing this infection. And, in conclusion, no matter what the differences of opinion are, the law of transportability remains absolutely established by all the facts yet obtained in regard to cholera.

Methods of Transportation of Cholera.—In a consideration of the question of the method of transportation of cholera, we are to look at two principal points, the agent of cholera, that is, the organism of the disease, and second, the medium.

The agent of cholera is unquestionably a bacterium, having India for its origin. It extends itself, and reproduces itself indefinitely, and many media serve as vehicles for its transportation throughout the entire world, but this choleraic agent would be wholly powerless if it did not encounter favorable conditions for its development. The medium, therefore, is indispensable to its power, and this favorable medium is made up of certain telluric conditions, the surroundings, and so on. So far as the methods of transportation of cholera are concerned, therefore, we have to consider more the medium in which it appears than the cause of the disease itself. Fauvel has expressed this truth as follows: "That a fire is not proportionate to the spark which gives it birth, but to the combustibility and mass of the material that it encounters." So, frequently, a few cases, or one only, as at Altenburg, are sufficient to produce the explosion of an epidemic.

The clinical consideration of the means of transportation of cholera is to be made under the following headings:

First, the transportation by men attacked by cholera, and the rôle played by the closets that have received choleraic excreta. A person arriving from an infected place is always necessary for the beginning of an epidemic. In other words, man himself is the most powerful agent for the spread of cholera, the specific microorganism being found, as has been demonstrated by innumerable experiments, in the excreta. Washerwomen have been attacked by the disease after washing linen soiled by evacuations, while others, who had simply touched this linen, also contracted the malady. Budd relates (quoted by Hirsch in *Schmidt's Jahrbücher*, vol. xcii., p. 255) that in 1854 a person affected with cholera arrived in an English factory of six hundred and forty-five workpeople. There followed one hundred and forty-four deaths from cholera in five weeks. The disease developed solely among those who made use of the closets where choleraic dejecta were deposited. Instances of this kind can be multiplied almost indefinitely.

Second, the transportation by means of choleraic diarrhœa. As illustrations of this, innumerable instances might be quoted, especially that mentioned by Budd in the reference given above. A person sick of diarrhœa came into the midst of a perfectly healthy population in a colliery, and died. Diarrhœa became general, and seventeen persons contracted cholera. The case of Dr. Alexander, in the *Gazette Médicale* for 1849, is also an illustration of this point. There was not at Hamel, a village twenty-five kilometres from Amiens, any indication of cholera, when, on April 4th, from Paris, where cholera existed, there arrived a soldier sick with diarrhœa. He was received into his parents' house where he remained three days. On the 14th he went to the Hôtel Dieu, and the same day his brother, who had come a number of times to see him, was attacked by foudroyant cholera and died in twelve hours. His wife died three days afterward. The father, who had shown some symptoms of cholerine, was attacked with cholera on the 11th, and died on the 15th. Another son of this man, seventeen years old, and a child of four years, his grandson, were attacked with cholera and got well. The father-in-law of the brother who had taken care of him and his daughter were attacked by cholera, but recovered. A child of eleven years, who was often at the house and whose parents had taken care of the same brother and his wife, was attacked on the 14th and died the following day.

Third, Can the bodies of persons dead of cholera communicate the disease? Although the evidence seems to point toward this being a possible danger, it is not a serious one in civilized countries.

Fourth, Can cholera be transported by healthy individuals? This must be answered in the negative. The facts quoted that seem to show that this may occur, must be explained by supposing that the individuals who were believed to be entirely well were in reality sick of a choleraic diarrhœa, or else that they carried clothing or linen soiled with choleraic material. The studies of cholera during 1892–93 in Europe have shown that the cholera vibrios may be present in the dejecta of people apparently healthy, with well-formed stools, as well as in those who are suffering from a mild diarrhœa without other notable symptoms. These vibrios were virulent and presumably capable of inducing severe cholera in more susceptible individuals.

Fifth, Can cholera be transported by living animals? Animals are not susceptible to the disease. A certain number of experiments have succeeded in producing cholera in animals, but with great difficulty. There is no fact to support the supposition that animals can carry the disease, either on the skin or in the hair.

Sixth, the transportation of cholera by means of clothing, personal effects, and so on. The disease cannot be so transported unless these materials have been contaminated by cholera dejecta. This, of course, is an exceedingly important point, for if soiled, the material may be dangerous: if it is not soiled, there is no danger at all, even if it comes from cholera centres. It is of equal importance to know whether contaminated objects have been packed up or exposed to the air. A contaminated object exposed to free air for a definite time loses its power of transporting the virus. The conference of Constantinople considered that a very short time was sufficient to do away with all danger, and recent bacteriological research has wholly confirmed this opinion. On the other hand, contaminated objects that have been packed up and kept shut out from the air retain their virulence for a greater or less length of time, as may be shown by many instances.

Seventh, Can cholera be transported by merchandise? Although merchandise imported from India, whether to Suez or directly to Europe, has never been known to transmit cholera, this method of transportation is not absolutely impossible, and many of the materials brought from India—cloths, and so on—retain in their interstices a confined air that certainly might preserve and transport for a great distance the contagion with which they may be impregnated; but although this is a possibility, it is not probable, and the conference of Constantinople unanimously accepted the absence of proofs of the transportation of cholera by merchandise, while it admitted the possibility of its being done, under certain conditions. Since that time, Zehnder, the Swiss delegate to the Vienna Conference, in 1874, cited facts in favor of the danger of rags in transporting contagion (see the report of the International Sanitary Conference of 1874, page 272). But at the conference in Rome, in 1885, Koch disputed the interpretation that had been put upon these facts.

Eighth, water is perhaps the most important agent in the spread of cholera, and evidence to this effect was obtained long before the discovery of the cholera spirilla. J. Simon brought out some facts in England which confirm this statement. At London thirteen deaths out of a thousand inhabitants occurred among those whose houses were supplied with river water in the neighborhood of the sewer. Tested at this point, the water yielded forty-six grains of solid residue to the gallon. In other houses in the city that were in the same hygienic condition, but not supplied with this water, the mortality was only three and seven-tenths in a thousand, but the water which they used had been taken from outside the city, and yielded only thirteen grains of solid residue to the gallon.

It is not improbable that the cholera vibrio can live longer in a pure water than in one containing large numbers of other micro-organisms. It has remained viable for eight hundred and seventy-eight days in a sterilized pond water, which for at least three hundred and five days contained other bacteria. During this period they retained their usual susceptibility to heat and desiccation, showing that a true spore formation of the usual kind is not necessary for prolonged viability in this species.

At Halle, Delbruck noticed that in the prison, where the epidemic had developed very largely, the wells communicated with the drains. At Brachsted the epidemic arrested itself just as soon as a suspected well was closed. Delbruck explained the less intensity of the epidemic of 1867, compared with that of 1866, by the fact that the carrying of the water had been modified. Water was furnished almost pure in 1867, while up to the autumn of 1866 the conduits carried the water from the Saale through a region where all the discharges of the city were scattered. Ballot also spoke of the influence of impure water on the spread of cholera in Holland. Snow, in England, and innumerable other writers in Europe, India, and America, lay the greatest possible stress upon impure water as the special means for the conveyance of the infective agent of cholera. (See the article on *Water*, in the present volume.)

The contamination of water played an extremely important part in the extension of cholera in Egypt in the epidemic of 1883. The Mussulman population of Egypt bathe very frequently, but they are not careful about the water that they use for drinking. At Damietta the water is exceedingly foul upon the points of the Nile from which the water-carriers fill their water-casks, and just at these places are the special spots selected for bathing. The houses along the bank discharge their foul material directly into the river, and drains carry to it discharges from other houses, and from the mosques. According to Koch, these mosques play an extremely important rôle in the spread of cholera. The German cholera commission was able at Damietta to examine a number of mosques, the description of the arrangement of which is as follows: Only that part of the mosque that is directed toward Mecca is used for prayers. At the other end is an open space, in the centre of which is a tank for bathing, and sometimes this water remains several weeks without being changed, and surrounding the basin are a series of urinals and closets. The discharges from the whole are passed into the Nile, so that it is not strange that the infected material should be transported by such a water supply.

In the "tank districts" of India the conditions appear particularly favorable for the propagation of cholera from the sick to the well. In these districts cholera is very prevalent. The region is low and the land upon which the dwellings are situated is made ground derived from the immediate neighborhood, leaving pools which constitute the "tanks." The drainage from the dwellings flows into these relatively or entirely stagnant bodies of water, which is also used for bathing and, in many cases, for drinking purposes.

The epidemic of 1884 furnished new proofs in favor of the spread of cholera through the agency of water. Messrs. Marey, Brouardel, and Thoinot especially insisted upon this point. Marey, at the sitting of the Academy of Medicine, October 14th, 1884, said: "Among the influences that can cause the spread of typhoid fever or cholera there is one that by its intensity dominates all the others—that is the contamination of public water supplies." If a number of epidemics of cholera be studied, it can be determined, in effect, that cholera easily follows watercourses; that it is especially along small watercourses that it is propagated, is most frequent and striking. In order to explain this, there are but two hypotheses that are possible.

First, brooks, torrents, or rivers flow in valleys that are often narrow and shut in, and the villages found there often can have no communication except with each other. When one is attacked, it is a perfectly simple matter that the others should be also in their turn. This explanation is very plausible; for certain cases, and some epidemics, can be explained in no other way. The great rivers, the large watercourses, along which are scattered regions attacked by cholera, serve for the propagation of this disease, like the great roads of travel, in this way only, that they are lines of communication frequented by travellers.

Second, water is certainly a propagating agent of cholera. It is the water of a torrent, a brook, or a small river, contaminated in one part of its course, that transports the disease to the inhabitants on its borders that drink of the water, and innumerable instances can be brought forward to illustrate this point also.

Proust (*loc. cit.*, p. 216) speaks of the choleraic agent having for its vehicle of transportation either the air or the water, but the evidence in favor of the air as one of the transporting agents of cholera is nothing, and the weight of scientific evidence of late years militates against such a means of transportation. Altitude seems to have but slight influence upon the development of the disease up to a certain point, although Farr (in the Registrar-General's Report on the Mortality of Cholera in England, London, 1852) has attempted to demonstrate that the mortality from cholera was in inverse proportion to the elevation. The objection to this is, that the less frequent occurrence of cholera on the most elevated points may be due to the fact that the less accessible points are more thinly inhabited.

Moisture, taken in connection with the subsoil water, is a favoring cause of the greatest importance, and observations in this direction have furnished the basis for Pettenkofer's theory of the connection of subsoil moisture with cholera.

The development of the epidemics of 1836 and of 1854 seemed to coincide with the period of greatest diminution of the subsoil moisture in Munich, and therefore the choleraic contagion with which the soil is impregnated appears to disengage itself more easily. Hirsch reached a similar conclusion. Kreuzer, in 1855, at Vienna, and again Pettenkofer, at Munich, observed the same facts. Pettenkofer's theory differs from others, in that, putting aside the chemical composition of the earth, he attaches a special importance to its physical characteristics, its density, its porousness, etc. He considers that the condition of the subsoil of localities and of houses plays a rôle of special importance in the propagation of cholera, and upon this special cause he places the development of an epidemic, after an importation from without; and, studying almost exclusively the physical condition of the region, the compact or porous condition of the subsoil, he considers that not only the primitive earth, and the soils of the transition period, but also the secondary formations, produce immunity when they are exposed to air in the condition of rocks. On the other hand, every porous soil that is susceptible of imbibition can become easily impregnated with fluid, or with gas, and vegetable earths as well as silicious earths may form "fat," always moist, lands, throwing out continual moisture about them, favoring the diffusion of the germs of cholera. Where the soil is made up of a compact calcareous rock cholera never becomes epidemic, and a few cases observed in such situations as the result of importation, do not propagate the disease.

Pettenkofer's theory has two points that must be distinguished from each other.

First, the nature of the soil. The soil must be porous, easily permeable, and also easily impregnated by liquids and gas. This condition is a permanent one.

Second, the level of the subsoil moisture. This level being movable, the effect is variable; when subterranean waters have reached the maximum of their elevation, there is neither decomposition of organic materials nor throwing off of miasms. If the subsoil moisture descends to a lower level putrefaction begins, the miasmatic vapors are thrown off more intensely, and just at this time the epidemic reaches its greatest development. This second point of his theory, certainly an ingenious explanation of certain cases, appears to be much more hypothetical than the first, the question of the porosity of the earth.

To sum up, Pettenkofer's theory, while it scarcely has the value ascribed to it by him, certainly seems to afford a partial explanation of the propagation of cholera by means of the porosity and moisture of the earth.

Ninth, amtospheric conditions play a not very important rôle, although the influence of season is manifest, and, apparently, storms sometimes seem to aggravate considerably an epidemic.

Somatic Conditions.—Race or nationality has no influence upon the development of cholera. The special influences favoring it are those of misery, fatigue, cold, and depressing mental conditions, which, by diminishing the resisting power of the body, render it more susceptible to the influence of the epidemic. Collections of human beings, in other words, agglomeration, play a very considerable rôle in the propagation of epidemics; so also do methods of transportation. Railroads are often the means of propagation, as was the case in the instance of Altenburg, quoted above. The epidemic of 1865, in Paris, was started by a woman who left Marseilles, with a choleraic diarrhœa, and was attacked with cholera upon her arrival in Paris. Transportation by caravans does not give much chance for the spread of the disease, when the distance passed over is of great extent; in fact, a great desert is the best of all obstacles to the propagation of cholera. In ships are most often found united the conditions of crowding and confinement favorable for the development of the choleraic agent.

Proust appears to believe that these elements do not have much potency if the entire ship's company come from the same infected region—in other words, have acquired an immunity in a choleraic focus; but if the ship's company has received a partial renewal, if new persons have come on board among the acclimated passengers, cholera finds a new favorable medium for attack, and, if aiding circumstances appear, the ship may become the centre of an intense epidemic. He goes on to speak of this "law of accustoming," in what takes place in armies, the great fairs, and the pilgrimages; for when cholera is carried into these great collections, if the mass of people have not undergone the "choleraic acclimating," the explosion of the disease is rapid and the mortality considerable, but only continues for a few days, and ceases soon. The Crimean War furnishes an example of the rapidity of development and intensity of the disease among vessels free from the choleraic influence.

At the commencement of April, 1855, there reached Constantinople from France, fifteen to twenty thousand troops, made up in part of the Imperial Guard. These troops had not, during their voyage, a single case of cholera among them. They camped on the heights of Masslak, in an extremely healthy situation, and at that time there were in the city of Constantinople but very few traces of cholera. The rolls of the French military hospitals gave only fifty-three cases during March, and the roll of April 11th showed none. In the Crimea the cases of cholera were also very few, and nevertheless the troops were hardly settled at Masslak when, on the night of April 14th and 15th, cholera broke out among them, and a severe epidemic followed.

Fauvel ("Memoire lu à l'Acad. des Sciences," Paris, 1883) sums up this question of immunity in the following propositions:

"1. The ports of India that are the seat of endemic cholera are never the scene of a great epidemic.

"2. This fact relates to the general, but not absolute, immunity enjoyed by the native population of these parts.

"3. This immunity does not exist in the endemic localities for strangers who are in a condition favorable for contracting the disease. These are especially the Mussulman pilgrims who come to Bombay to embark for Mecca.

"4. The epidemics of cholera that develop in India, in the regions where the disease is not endemic, come from the places where it is endemic, and are favorable for attacking the Hindoo pilgrimages.

"5. The epidemics observed among the pilgrims to Mecca can also be traced to the localities where cholera is endemic.

"6. A severe epidemic of cholera confers upon the country or upon the locality which it has attacked a more or less complete immunity, which is more or less durable, and of which it is impossible to formulate the law for Europe, but which in India appears to last for a number of years.

"7. In the Hedjaz, and in the sparsely populated parts of Arabia, cholera has but a feeble tendency to propagate itself among the native population.

"8. The fact of the existence of a great epidemic of cholera in any country whatever is a proof that cholera is not there endemic."

To sum up, new scientific facts bear upon the question of immunity and make them clear upon a side hitherto unknown. The etiology and prophylaxis, in especial, of cholera receive from these facts new indications, and these facts also appear to be the expression of a law that includes an entirely different category of infectious diseases, which leave after them an immunity of a greater or less extent.

Period of Incubation.—The question of the period of incubation of cholera gives rise to a great deal of discussion. It appears, however, that in the immense majority of cases a period of a few days is sufficient for the incubation, and that sometimes this may require only a few hours. This fact is easy to observe if the beginning of the disease in a city or upon a ship be studied.

The Cholera Conference at Constantinople concluded as follows: "That all the facts cited in regard to a period of incubation longer than a few days are based upon cases that are not conclusive, either because the premonitory diarrhœa was comprised in the period of incubation, or because the infection could have occurred after the departure from the infected locality." The following is an instance:

On November 3d, 1848, upon the ship *Swanton* there were two hundred and eighty-nine emigrants for New Orleans, and the cholera did not break out on board until November 25th—that is to say, the twenty-third day of the voyage—and occasioned thirteen deaths. A certain number of these emigrants came from points in Germany where the cholera existed. This long period of incubation can be explained upon two hypotheses: either the passengers had with them clothing soiled with choleraic materials, which, placed in a confined air, could transmit cholera; or certain of the individuals embarked might have been affected at the time of their embarkation with a diarrhœa that might later have developed into true cholera. The duration of this premonitory diarrhœa has been much discussed, and in general it has been concluded that it does not last more than three days, and when it does pass this period, it is rarely prolonged beyond a week, and that therefore an individual isolated from all sources of contamination, and in whom the diarrhœa should be prolonged more than eight days after this isolation without presenting any characteristics of cholera, could be considered non-choleraic. But Griesinger among others dissents from this opinion, and declares that the period of incubation of cholera may be much longer. A bacteriological examination furnishes the only method of settling the question.

The experience of those who carefully studied the epidemic in Hamburg in 1892–93 points to an incubation of not less than twenty-four hours. After this period there may be a diarrhœa which attracts little attention, but which is in reality the first stage of the disease. In other cases the onset of symptoms may be very sudden, leading to collapse and death within a few hours. It has been noted that in the early days of an epidemic the spirillum develops more slowly in artificial media than is the case later in the course of the epidemic.

DESCRIPTION OF THE DISEASE.—The clinical manifestations associated with the presence of the cholera vibrio in the intestinal contents are so various that it is impossible to give a single clinical picture of Asiatic cholera. During epidemics of the disease this micro-organism has frequently been isolated from the fæces of people presenting no evidence of any disturbance in health. In other cases its presence is associated with symptoms of the most marked character, followed by a speedily fatal issue. These facts by no means throw doubt upon the etiological significance of the cholera vibrio; for similar observations are well known in other infectious diseases, such as diphtheria, typhoid fever, and even infections with pyogenic micro-organisms.

Cases in which the cholera vibrio is present in the digestive tract without being associated with symptoms are of great sanitary importance, because this very absence of all manifestations of disease renders the spread of the infection from place to place very difficult of control or detection. It is also important to the individual himself. There are cases on record in which people in apparently perfect health have left regions where cholera was epidemic, have remained for a time free of any signs of ill health, and then, as the result of some dietary indiscretion, have suddenly succumbed to an attack of severe cholera, with the vibrios in the alvine discharges. It appears evident that in such cases the cholera vibrios in the intestine are virulent, but that the resistance of the individual was so great as to prevent the usual effects of infection until some additional factor created a susceptibility. It is not possible to state the frequency of such latent infections in times of epidemic cholera, but where the spread of the disease takes place through a contaminated water supply it is reasonable to suppose that they must be more frequent than could be indicated by any statistics as yet in existence. Rumpf, in his studies of the epidemic in Hamburg in 1892–93, reports that cholera vibrios were found in the fæces of 62 individuals during the small after-epidemic of 1893, and that of these 19 failed to show signs of any great constitutional disturbance. These cases were studied because they had been closely associated with cases of pronounced cholera in the city or upon vessels in the port. On the other hand, between February 23d and June 1st, 1893, 70 cases of diarrhœa were investigated to learn of the presence of cholera vibrios in the discharges, with negative results.

Leaving out of further consideration these important latent infections, we may divide cases of cholera into three groups, according to the severity of the clinical manifestations: First, choleraic diarrhœa, in which the symptoms present little beyond a marked looseness of the bowels; second, cholerine, characterized by vomiting and considerable constitutional disturbance as well as diarrhœa with rice-water discharges; and, third, algid or asphyctic cholera or cholera gravis, which has hitherto served as the type of the disease.

These terms are not used to denote nosological entities, but merely to furnish concise expressions for clinical differences dependent upon variations in the relations between the virulence of the infection and the susceptibility of the patient. In individual cases the less severe forms of the disease may pass into the graver types, where conditions arise which modify these relations. In many epidemics the milder types occur most frequently early in the history of the epidemic, to be succeeded by a larger percentage of severe cases at the height of the epidemic, which are in turn followed by a preponderance of the milder cases as the epidemic draws to a close. These clinical observations harmonize with the experience that cultures in artificial media grow less rapidly early and late in an epidemic than at its height.

Choleraic Diarrhœa.—In the milder cases the stools are feculent or bile-stained and watery, are unaccompanied by much pain, and differ considerably in frequency in different cases. The symptoms usually first appear at night and are accompanied by some flatulence. The general health may remain good. In severer cases the stools are more numerous; the appetite is lost; the tongue becomes coated, and there is a feeling of gastric depression. The amount of urine is decreased. The patient becomes restless and suffers from headache. Dragging pains in the calves may be troublesome. These symptoms last a few days, and in favorable cases then subside. The course of the affection depends largely upon collateral circumstances. Indiscretions in diet, over-fatigue or imprudence of any kind exert an unfavorable influence upon the patient, and in many cases this choleraic diarrhœa passes into the severer forms of cholera. Although the cholera vibrios are regularly found in the discharges, the latter do not acquire the rice-water character typical of the severer forms of the disease.

The affection may prove fatal in people of diminished resistance; in the young or aged death being the result of exhaustion; but recovery is the rule.

Cholerine.—Sometimes this type of cholera is preceded by the form just described, but more often the first symptoms noted are general malaise, loss of appetite, and nausea. The stools then become more frequent. They are at first feculent, but soon become more liquid and then assume the "rice-water" character of those in severer cases of cholera. These discharges consist of a serous fluid, rendered turbid by large quantities of desquamated intestinal epithelia, and frequently tinged more or less pinkish by red blood corpuscles. When examined microscopically the spirilla may frequently be seen in great numbers, but in many cases they cannot be made out as such, but appear as granules of various shapes. In addition to the symptoms mentioned above, vomiting comes on early in this form of the disease. After the stomach is emptied of food, the vomitus is a thin fluid containing some bile, or it may be colorless. Pain in the epigastrium, headache, and thirst appear as the disease progresses. The quantity of urine is reduced and albuminuria appears. The skin is cool and the volume of the pulse diminished.

Cholerine may pass into algid cholera, or the symptoms may gradually subside and recovery follow; but not infrequently convalescence is delayed by a long period of debility and mental hebetude, resembling the typhoidal stage of algid cholera.

Cholera Gravis; Algid or Asphyctic Cholera.—In this form, which has usually been regarded as the typical manifestation of the disease, the attack may suddenly develop, its onset being marked by great uneasiness, repeated discharges from the bowels, followed by syncope. This attack may overtake the victim while walking on the street in apparently good health. It is often preceded by a state of vague suffering, rapid prostration, deep colicky pains, anorexia, sometimes a diarrhœa, profuse sweats, disturbance of the senses, and more or less retardation of the pulse. After the development of the disease the symptoms follow each other in such a way as to allow of a division into two distinct periods.

First Period.—This is marked by an increase in the number of dejections and acts of vomiting; a flux is established which is at first serous or slightly bilious, and afterward becomes "choleraic." This term is used to designate those characteristic discharges of cholera which are liquid, whitish, grumous, sometimes resembling unclarified whey, sometimes a decoction of rice or oatmeal, and sometimes thickened meal, and nearly clear, which emit an insipid spermatic odor, and sometimes present traces of blood or bile. These evacuations are rarely absent, often continuing to the termination of the disease. Burning thirst, pain in the epigastrium, and prolonged hiccough are usual accompaniments. Intense cramps of the limbs occur, particularly in the calves of the legs; the muscles are often in a state of tonic contraction. Spasmodic movements, as involuntary flexion and extension of the fingers and toes, may often be seen. The pulse is very feeble, often imperceptible. The features are altered, trembling and great agitation come on, the pulse becomes suppressed; bluish spots appear, first upon the extremities; the skin becomes blue or black almost everywhere; the nails are livid and almost black, the fingers wrinkled, and the genital organs retracted. The volume of the body diminishes rapidly and perceptibly; the eyes sink in and are dull, with a bluish circle surrounding them; the conjunctiva fades, respiration is slow and feeble, the breath cold, and the pulse is reduced to a mere oscillation. The secretions are arrested, especially the urine, the voice is reduced to a whisper, the nose is cold and—rarely—gangrenous, the cornea is flattened and puckered; spots of blood appear on the sclerotic, viscid sweat on the face and limbs; the intellect becomes obscured, respiration is embarrassed, hiccough commences, and death follows, in the midst of an apparent calm. This is called the *cold, livid,* or *asphyctic* period. When patients escape death in this stage they enter upon the

Second Period.—In this the coldness ceases to increase, warmth returns, the pulse improves and gradually becomes febrile, the face regains color, the eye becomes animated, and a general reaction occurs.

If recovery is to be easy and rapid, vomiting becomes less frequent, the diarrhœa remains, but the discharges no longer present the appearance peculiar to the disease; the secretion of urine returns, nausea, thirst, and pains in the stomach cease to be felt, the pulse becomes regular, and convalescence begins.

If reaction is incomplete, the cold stage returns with renewed severtiy, or, on the other hand, if reaction be too severe, such accidents may occur as apoplexies, spasms, convulsions, local congestions and inflammations, and occasionally latent pneumonia. Stupor is sometimes present, with some of the signs of the last stage of typhoid fever. Swelling of the parotid glands and various skin affections, as roseola, urticaria, erythema, erysipelas, etc., may appear toward the close of the disease.

The average duration is from one to three days, but sometimes death occurs in less than six hours, and is occasionally delayed a long time—in one case for fifty days.

Complications and Secondary Affections.—Complications are rare, and apparently accidental, but secondary affections, either direct results of the cholera or due to increased susceptibility to infection or to debility, are common.

Course, Duration, and Termination.—If death does not occur during the algid stage, a peculiar transformation in the disease takes place and *reaction* sets in. This reaction varies in different cases, being slow and tedious in some, and abrupt and rapid in others; its course is not essentially modified by any antecedent disease, even those occurring as complications.

In the vast majority of cases cholera runs its course with great rapidity, the greater number of attacks lasting from eighteen to twenty-four hours, the shortest from one to six hours, and the longest from fifteen to twenty days. Its duration is the shortest at the height of an epidemic.

The termination of epidemic cholera may be favorable, the progress of recovery varying widely in different cases; it may be complete in a few hours even, and the patient may return to his ordinary occupation; on the other hand, it may be delayed until after a long and perilous struggle against complications and secondary affections. There may remain a general debility such as is not often seen after any other disease; the emaciated features, languishing expression, capricious appetite, obstinate gastralgia, colic, wakefulness, tendency to coldness, partial or general, and intellectual and moral dejection persist for a long time. An attack has been known to change the whole constitution and temperament of a patient. One attack appears to furnish no immunity against another, and relapses are always to be feared.

SYMPTOMS IN DETAIL.—Besides this general account of the disease the symptoms should be briefly discussed in the order of their occurrence.

Precursory Phenomena.—An attack is often preceded by initiatory uneasiness, which should attract attention; such are languor, pallor, anxious expression, sunken features, weight in the stomach, and movements of the intestines. Then vertigo follows, with abdominal pain, dimness of vision, and difficulty of hearing; the eyes become more brilliant than ordinary, like those of a drunken man. Sometimes circulatory disturbances are the first phenomena of the disease, marked by bluish circles around the eyes. In other cases, the progress of the preliminary symptoms differs—there are diminution of appetite for several days, general disagreeable sensations, and frequent alvine dejections, without pain, which are yellowish, more and more fluid, and, finally, become almost like water. A diarrhœa like this may occur without any other symptoms and develop into a severe case of cholera. Lastly, the disease may come on suddenly, and without warning overwhelm the victim with its full force—this often occurring at night.

Diarrhœa.—Thi. is most frequently the mark of the onset of the disease, and when it is so, the stools become at once more and more frequent. Fifteen, twenty, or more dejections in twenty-four hours are usual, and in some cases (these are fatal) the evacuations occur in an almost continuous and involuntary jet. They are often accompanied by colic, borborygmi, and gurgling, either spontaneous or excited by pressure upon the abdomen. They are at first made up of bilious, fæcal, or sero-mucous matter, but soon assume the characteristic appearance, viz., that of a whitish flocculent fluid such as has already been described. A large flocculent sediment is deposited from this fluid, a part of it looking remarkably like cooked rice. The fluid is blood-serum, and the sediment is made up of the epithelial lining of the intestines and of mucus. Sometimes the evacuations are tinged with blood-coloring matter, giving them the appearance of the lees of wine, or they may be of a deep brownish color from the same cause. The frequency of the dejections is not always increased with the progress of the disease, they are occasionally completely arrested during the cold period, and death may occur without their beginning again; on the other hand, they may return with increased violence. In those cases in which the acute attack is followed by a prolonged period of depression, during which the patient presents the typhoid state, the choleraic discharges give place to loose, diarrhœal evacuations having a fæcal odor. These may be frequent and persist for a number of days, gradually diminishing as convalescence advances;

On November 3d, 1848, upon the ship *Swanton* there were two hundred and eighty-nine emigrants for New Orleans, and the cholera did not break out on board until November 25th—that is to say, the twenty-third day of the voyage—and occasioned thirteen deaths. A certain number of these emigrants came from points in Germany where the cholera existed. This long period of incubation can be explained upon two hypotheses: either the passengers had with them clothing soiled with choleraic materials, which, placed in a confined air, could transmit cholera; or certain of the individuals embarked might have been affected at the time of their embarkation with a diarrhœa that might later have developed into true cholera. The duration of this premonitory diarrhœa has been much discussed, and in general it has been concluded that it does not last more than three days, and when it does pass this period, it is rarely prolonged beyond a week, and that therefore an individual isolated from all sources of contamination, and in whom the diarrhœa should be prolonged more than eight days after this isolation without presenting any characteristics of cholera, could be considered non-choleraic. But Griesinger among others dissents from this opinion, and declares that the period of incubation of cholera may be much longer. A bacteriological examination furnishes the only method of settling the question.

The experience of those who carefully studied the epidemic in Hamburg in 1892–93 points to an incubation of not less than twenty-four hours. After this period there may be a diarrhœa which attracts little attention, but which is in reality the first stage of the disease. In other cases the onset of symptoms may be very sudden, leading to collapse and death within a few hours. It has been noted that in the early days of an epidemic the spirillum develops more slowly in artificial media than is the case later in the course of the epidemic.

Description of the Disease.—The clinical manifestations associated with the presence of the cholera vibrio in the intestinal contents are so various that it is impossible to give a single clinical picture of Asiatic cholera. During epidemics of the disease this micro-organism has frequently been isolated from the fæces of people presenting no evidence of any disturbance in health. In other cases its presence is associated with symptoms of the most marked character, followed by a speedily fatal issue. These facts by no means throw doubt upon the etiological significance of the cholera vibrio; for similar observations are well known in other infectious diseases, such as diphtheria, typhoid fever, and even infections with pyogenic micro-organisms.

Cases in which the cholera vibrio is present in the digestive tract without being associated with symptoms are of great sanitary importance, because this very absence of all manifestations of disease renders the spread of the infection from place to place very difficult of control or detection. It is also important to the individual himself. There are cases on record in which people in apparently perfect health have left regions where cholera was epidemic, have remained for a time free of any signs of ill health, and then, as the result of some dietary indiscretion, have suddenly succumbed to an attack of severe cholera, with the vibrios in the alvine discharges. It appears evident that in such cases the cholera vibrios in the intestine are virulent, but that the resistance of the individual was so great as to prevent the usual effects of infection until some additional factor created a susceptibility. It is not possible to state the frequency of such latent infections in times of epidemic cholera, but where the spread of the disease takes place through a contaminated water supply it is reasonable to suppose that they must be more frequent than could be indicated by any statistics as yet in existence. Rumpf, in his studies of the epidemic in Hamburg in 1892–93, reports that cholera vibrios were found in the fæces of 62 individuals during the small after-epidemic of 1893, and that of these 19 failed to show signs of any great constitutional disturbance. These cases were studied because they had been closely associated with cases of pronounced cholera in the city or upon vessels in the port. On the other hand, between February 23d and June 1st, 1893, 70 cases of diarrhœa were investigated to learn of the presence of cholera vibrios in the discharges, with negative results.

Leaving out of further consideration these important
latent infections, we may divide cases of cholera in
three groups, according to the severity of the
manifestations: First, choleraic diarrhœa, in which
symptoms present little beyond a marked
the bowels; second, cholerine, characterized by
and considerable constitutional disturbance
diarrhœa with rice-water discharges; and,
or asphyctic cholera or cholera gravis, which
served as the type of the disease.

The heart [illegible] oft and flabby, the muscle degenerated, with [illegible] in the pericardium. The left side is apt to [illegible] and contracted, the right distended with dark, [illegible] od. The arteries are, in general, nearly empty. [illegible] is distended with blood. The pleuræ are very [illegible] tly coated with a glutinous, stringy substance, [illegible] chymoses often appear in the subpleural cellular [illegible]. The lungs are usually healthy, but presenting [illegible] gements at the posterior portions; or they may con- [illegible] pneumonic areas or abscesses due to inhaled vomi- [illegible] The bronchi are much congested, and may contain [illegible], stringy mucus, analogous to that found lining [illegible] stinal canal. The condition of the brain and spi- [illegible] d, together with their appendages, is merely that [illegible] stion without special lesion, although it has been declared that there is a sensible increase in their consistence. The ganglionic system presents no change worthy of notice. The muscles are often engorged with blood, and a very marked reddish-brown discoloration of the bones and of the teeth has been noticed in those dying of asphyxia. Renal congestion is the marked alteration in connection with the genito-urinary tract, and the straight tubules are often completely stripped of their epithelium. The epithelium of the convoluted tubules suffers marked parenchymatous degeneration, even in cases of short duration. In those dying in the cold stage the bladder is empty and firmly contracted. The uterus usually shows a hemorrhagic endometritis, and abortion is the rule in pregnant women.

Description of the Spirillum of Cholera.—Asiatic cholera is without doubt due to a special organism—the so-called "comma bacillus" of Koch—this name being a misnomer, for the bacterium is not a bacillus, but a spirillum.

The parasitic nature of the disease was suspected for a long time. A number of observers had noted the presence, in the cells, of bacteria answering the description of this special one, but it was not until the advance in methods of observation had progressed a long way that it was possible to isolate the organism, and study it under artificial conditions in such a manner as to obtain the evidence necessary to connect it with the process as a causal factor. It was in the year 1883 that Koch first discovered and described the spirillum of Asiatic cholera, which he first found during his investigation in Egypt during the epidemic there, and studied further during the following winter in India.

The organism occurs especially in the small intestine, is generally wholly confined to the contents of the intestine and the glandular culs-de-sac, but is occasionally found in the intestinal walls. It is exceptional to find it in any other part of the body, and it is not strange that investigations undertaken with the idea that cholera was a generalized disease were not productive of results. The bacterium is found in large quantities in the dejecta, and sometimes—in fact not infrequently—in almost a pure culture.

In the intestines and in the dejecta it presents the appearance of a short, thick rod, slightly curved in the long diameter, hardly half as long, but considerably thicker than the bacillus of tuberculosis. It usually occurs in this situation singly, but not infrequently it is arranged in pairs, with the curves opposed to each other, and thus recalling the shape of the letter "**S**." There are many exceptions to this rule, and a simple microscopical examination of the dejecta does not suffice to establish a diagnosis of Asiatic cholera, or to exclude such a diagnosis. Sometimes no curved, **S**-shaped, or spiriliiform organisms are seen, but the preparation contains numerous granules of various shapes. If, however, plate cultures are made from these discharges, they may yield practically pure cultures of the cholera spirillum. Even when very small quantities of the dejecta are used, the colonies may crowd the plates. Under cultivation in bouillon the organism appears longer and thinner, and there are many true spirilla to be seen in the preparations made from such a culture. (See Plate LIX.)

A characteristic that is of especial interest is its extreme motility, which has been demonstrated by Löffler to be due to a fine cilium or two, occasionally three cilia, which are longer than the bacteria, placed at one end of the organism. Shortly before division, both ends possess cilia. After prolonged artificial cultivation the motility is reduced in activity.

Shape and motility are not, however, sufficient to differentiate this bacterium from others with similar characteristics—and there are many that possess such—but the method of development upon the various culture media is entirely characteristic, and, as shown by Koch, is all that is necessary for separating this one in particular from the others that resemble it. It liquefies gelatin, but it does this slowly, and at the same time a certain part of this liquefied portion evaporates, and as a result there is a special appearance of the culture that is shared by only a few other spirilla. At the upper portion of the gelatin there is a round cavity full of air, and as the surrounding gelatin has remained solid, the appearance is that of a bubble of air in the midst of the upper part of the gelatin and above the liquefied part. The appearance is wholly different when the organism found by Finkler is put under the same conditions, and equally so with the cheese spirillum of Deneke. The spirillum of Metschnikoff grows in very similar fashion in stab cultures in gelatin, and there have been isolated from water and other sources spirilla which cannot be distinguished from the cholera vibrio in this culture medium.

Morphology.—Slightly curved rods, with rounded ends, from 0.8 μ to 3 μ long, and about 0.3 μ to 0.5 μ broad. They are usually but slightly curved, like a comma, but are occasionally in the form of a half-circle, or two united rods curved in opposite directions, forming an **S**-shaped figure. Under certain circumstances these curved rods may develop into long spiral filaments, and in hanging-drop cultures the **S**-shaped figures may also be seen to form the commencement of a spiral. In stained preparations the spiral character of the long filaments is often obliterated, or nearly so. When development is very rapid, the short curved rods, or **S**-shaped spirals, only are seen, but in hanging-drop cultures, or in media in which the development is retarded by an unfavorable temperature, the presence of a little alcohol, and so on, the long spiral filaments are quite numerous, and it is quite generally agreed that the so-called comma bacillus is really only a fragment of a true spirillum.

By Löffler's method of staining, the rods may be seen to have from one to three terminal flagella. In old cultures the bacilli frequently lose their characteristic form, and become variously swollen and distorted. Hueppe has described the appearance in the course of the spiral filaments, of spherical bodies which he believes to be reproductive elements, the so-called arthrospores. These bodies are not functionally spores; for cultures containing them are no more resistant than those which contain spirilla without these bodies. The cholera bacillus stains with the usual aniline colors, but not so quickly as many other bacteria. It is best stained by a watery solution of fuchsin. It will not stain by Gram's method. Sections may be stained by Löffler's methylene blue.

Biological Characters.—It is an aërobic, facultative anaërobic, liquefying, motile spirillum, grows in the usual culture media at the room temperature, more rapidly in the incubator, does not develop above 42° C. or below 14° C., does not form endogenous spores. In gelatin plate cultures, at 22° C., at the end of twenty-four hours small white colonies may be perceived in the depth of the gelatin. These grow toward the surface, and cause liquefaction of the gelatin in the form of a funnel that gradually increases in depth, and at the bottom of which is seen the colony, in the form of a small white mass. As a result of this, the plates on the second or third day appear to be perforated with numerous small holes; later, the gelatin is entirely liquefied. Under a low power, the young colonies, before liquefaction has commenced, present a somewhat characteristic appearance. They are of a white, or pale yellow color, with a more or less irregular outline, the margins being rough and uneven; the texture is coarsely granular, and the surface looks as if it was covered with little fragments of broken glass, while the colony has a shining appearance. When liquefaction commences, an ill-defined halo is first seen to surround the granular colony, which by transmitted light has a peculiar roseate hue.

In gelatin needle cultures development occurs all along the line of inoculation, but liquefaction of the gelatin occurs at first only near the surface. On the second day, at 20° C., a short funnel is formed that has a comparatively narrow mouth, the upper portion containing air; just below this is the whitish viscid mass of the growth. At the end of from four to six days, the funnel, having increased in depth and diameter, may reach the walls of the test tube. In from eight to fourteen days the upper two-thirds of the gelatin is completely liquefied. Owing to the slight liquefaction occurring along the line of growth the first three or four days, the central mass that has formed along the line of inoculation settles down as a curved or irregularly bent yellowish-white thread, in the lower part of a slender tube filled with liquefied gelatin, the upper part of which widens out, and is continuous with the funnel above. (See Fig. 5 of Plate LIX.)

On the surface of nutrient agar a moist, shining, white layer is formed along the line of inoculation. Blood serum is slowly liquefied. On potato in the incubator, a rather thin semitransparent brown, or grayish-brown layer is developed.

In nutrient bouillon the development is abundant and rapid, especially in the incubator. The fluid is only slightly clouded, but the spirilla accumulate at the surface, forming a wrinkled membranous layer.

Sterilized milk is also a favorable culture medium. The milk, however, is not visibly altered by the growth of the bacilli.

In general this organism grows in any fluid containing a small quantity of organic material and having a slightly alkaline reaction. An acid reaction of the culture medium prevents its development as a rule, but it has the power of gradually accommodating itself to the presence of vegetable acids, and grows upon potatoes (in the incubator only) which have a slightly acid reaction. Abundant development occurs in bouillon which has been diluted with eight or ten parts of water, and the experiments of Wolffhügel and Riedel show that it also multiplies to some extent in sterilized river or well water, and that it preserves its vitality in such water for several months, but in milk or water containing other bacteria it dies out in a few days. This organism is destroyed, in recent cultures, in nutrient gelatin at 52° C., as determined by Sternberg, the time of exposure being four minutes. A few colonies only develop after exposure to a temperature of 50° C. for ten minutes. In Kitasato's experiments ten or even fifteen minutes' exposure to a temperature of 55° C. was not always successful in destroying the vitality of the spirilla, although in certain cultures exposure to 50° C. for fifteen minutes was successful. The low resisting power to heat, desiccation, and chemical agents, indicates that this organism does not form spores, and most bacteriologists agree that this is the case.

Hueppe has described a mode of spore formation which is different from that occurring among the bacilli, that is, the formation of so-called arthrospores. These are said to be developed in the course of the spiral threads, not as endogenous, refractive spores, but as spherical bodies with a somewhat greater diameter and somewhat more refractive; but this method of spore formation has not been observed by others who have investigated the question, and cannot be considered established.

The test for the presence of the cholera spirilla originated by Bujwid and by Dunham consists in the reddish-violet color produced in the bouillon cultures containing peptone, or in cultures in nutrient gelatin when a small quantity (five to ten per cent.) of sulphuric acid is added to the cultures. According to Fraenkel this test serves to distinguish it from the ordinary bacteria of the intestine, and from the Finkler-Prior spirillum, but not from Metschnikoff's spirillum. The reaction is shown by bouillon cultures which have been in the incubator for ten or twelve hours, and by gelatin cultures in which liquefaction has occurred. The sulphuric acid should be quite pure. The color quickly appears, and is reddish-violet or purplish-red. According to Salkowski, the red color is due to the well-known indol reaction, which in cultures of the cholera spirillum is exceptionally intense and rapid in its development.

The most satisfactory method for obtaining the "cholera-red" reaction—as we have had lately abundant opportunity to verify—is that of Beyerinck ("Cat. f. Bact. ü. Parasit.," Bd. xii., S. 715) in which cultures are made in filtered neutralized one-half-per-cent. solution of commercial peptone, at 37° C. After twelve to twenty-

(AFTER KOCH AND GAFFKY.)

four hours the cultures are cooled, and from two to five drops of chemically pure sulphuric acid are added. If the spirillum be present, a very marked and beautiful rose-violet color is produced in the course of a few moments. In peptone-water cultures this indol reaction is perceptible as soon as the faintest clouding of the medium can be observed. Four to six hours' incubation at 37° C. may suffice.

A test which is said to distinguish cultures of the cholera spirillum from the spirillum of Deneke and that of Finkler-Prior has been suggested by Cahen. This consists in adding a solution of litmus to the bouillon, and in making the cultures at 37° C. The cholera cultures show on the following day a decoloration which does not occur at this temperature with the other spirilla named. For determining as promptly as possible whether certain suspected excreta contain the cholera spirilla, a little of the material may be used to inoculate greatly diluted bouillon, or a one-per-cent. peptone, one-half-per-cent. salt solution, gelatin plates being made at the same time. At the end of ten or twelve hours the cholera spirilla, if present, will already have formed a characteristic wrinkled film upon the surface of the bouillon. A little of this should be used to start a new culture in bouillon, and a series of gelatin plates made from it, after which the indol test may be applied. In the peptone solution mentioned above, the cholera spirilla seek the surface of the medium, and if cultivated at 37° C. a little of the material may be taken with a loop from the surface at the expiration of three hours and used for plate cultures or for examination in the hanging drop. The result of this, in connection with the morphology of the micro-organisms forming the film, and the character of growth in the gelatin plates, will establish the diagnosis, if the cholera spirillum is present in considerable numbers; if but few are present in the original material it may be necessary to make two or more series of plates and bouillon cultures before a pure culture can be obtained, and a positive diagnosis made. These tests will suffice for the purpose in times of epidemic cholera, but when there is doubt concerning the existence of cholera in the region, more rigorous identification is desirable. The virulence of the cultures may be tested on guinea-pigs and the agglutinative test with the serum of immunized animals applied.

Pfeiffer has shown that recent aërobic cultures of the cholera spirillum contain a specific toxic substance fatal to guinea-pigs in extremely small doses. This substance stands in close relation with the bacterial cells, and is perhaps an integral part of the same.

The spirilla may be killed by chloroform, by thymol, or by desiccation without apparent injury to the toxic character of this material. It is destroyed, however, by absolute alcohol, by concentrated solutions of neutral salts, and by the boiling temperature, and secondary products are formed which have a similar physiological action, but are from ten to twenty times less potent.

Similar toxic substances were obtained by Pfeiffer from cultures of the Finkler-Prior spirilla, and from the spirilla of Metschnikoff.

The spirillum is not found in the blood, nor in the various organs of individuals dead of cholera, but is always found in the discharges during life, and in the contents of the intestines examined immediately after death, frequently in almost a pure culture in the colorless rice-water discharges. They may persist in the discharges for twenty-three or more days, but usually disappear from the ninth to the twelfth day of the disease. Occasionally they may fail to appear in cultures for one or more days during the attack. It is evident that the morbid phenomena must be ascribed to the absorption of toxic substances formed during the growth of the spirillum in the intestine. In cases which terminated fatally after a very brief sickness Koch found but very slight changes in the mucous membrane of the intestine, which was slightly swollen and reddened; but in more protracted cases the follicles and Peyer's patches were reddened about their margins, and an invasion of the mucous membrane by the organisms was observed in properly stained sections. They penetrated especially the follicles of Lieberkühn, and in some cases were seen between the epithelium and the basement membrane. As a rule, the spirillum is not present in vomited material, but there are numerous exceptions to this rule on record. All observers have found the organism always present in cases of true cholera; on the other hand, very numerous control experiments fail to show its presence in the intestinal contents of healthy persons, when cholera is not prevalent, or in that of those dead from other diseases.

Nicati and Rietsch observed a certain degree of attenuation in the pathogenic power of the spirillum, after it had been cultivated for a considerable time at from 20° to 25° C., and the observation has since been made that cultures which have been kept up from Koch's original material have no longer the original pathogenic power. They also gradually change in biological characters upon prolonged cultivation, the colonies on gelatin plates being much less glistening and granular.

The organism most likely to be confounded with the cholera spirillum, and from which it must be differentiated by the methods of cultivation, as well as by the aid of the microscope, is the spirillum of Finkler-Prior, otherwise called the vibrio proteus. It was obtained by Finkler and Prior in 1884, from the fæces of patients with cholera nostras, after allowing the dejecta to stand for some days. Subsequent researches have not sustained the view that this spirillum is the specific cause of cholera nostras. Besides this spirillum many others, more or less resembling the spirillum of cholera, have been isolated. With the exception of the vibrio of Ivanoff (Migula), an organism incidentally isolated from the stools of a patient suffering from typhoid fever, none of these spirilla agglutinate with cholera immune serum. The colonies of this vibrio, however, do not closely resemble those of cholera on gelatin plates, being less granular and more filamentous.

Despite the numerous controversies on the subject since the first announcement by Koch that he considered his spirillum to be the cause of cholera, and the many assertions to the contrary, the relationship between the two is to-day admitted by practically all authorities. The opinion to this effect is based upon a number of reasons, some of which are as follows:

1. The spirillum of Koch has never been found in any other disease, a point that has been established by innumerable observations.

2. This spirillum is found in all cases of Asiatic cholera, without exception, provided that the case is not too far advanced. In such a case there has been a secondary infection, that has killed out the true organism and masked its effects. Ever since the first announcement of this discovery by Koch, observers have verified his assertions in all parts of the world where cholera has been investigated.

3. This spirillum is found in slight cases as well as in severe. It is present in the beginning of the attack, and it is located in the intestine, that is to say in the region especially attacked by the disease, and in which occur the initial and essential lesions.

The attempts to add to these arguments the more decisive one of successful inoculation experiments, were at the first not satisfactory in their results. Nicati and Rietsch were the first to secure successful results, which they obtained by introducing pure cultures of the organism into the duodenum of guinea-pigs, in which animals they had previously tied the ductus choledochus. By these experiments they obtained symptoms extremely analogous to those of true cholera, and Koch also succeeded in the same direction by passing the infectious material (pure cultures) into the stomach by an œsophageal catheter. In his experiments the animals had been previously narcotized by the injection of tincture of opium, to prevent peristalsis, and their stomachs had been made alkaline by the introduction of carbonate of soda, a solution to make the contents of the stomach alkaline being necessary, because the spirillum of Asiatic cholera will not develop in an acid medium.

Doyen has shown that by introducing alcohol into the stomach the alkaline solution and the tincture of opium may be dispensed with. But, however the experiments may be conducted, they all show one important thing—the great necessity for a healthy condition of the gastro-intestinal tract for the avoidance of infection with cholera. Dyspeptics and alcoholics have been shown in all epidemics to be especially fatally attacked by the disease. It cannot yet be affirmed that the absolute proof of the production of cholera by the specific spirillum has been obtained, because the methods employed in the experiments mentioned above leave too many loop holes open for the occurrence of accidents, and yet the evidence is so nearly complete that there seems to be no reason for any doubt; the more especially as the exact experimental evidence can probably never be obtained, because none of the lower animals, so far as is known, are susceptible to cholera under natural conditions. The nearest approach to an actual experiment upon man is the case of one of the members of one of the cholera courses held in Berlin in the winter of 1884–85. This man, a physician, was attacked with "cholerine," and after some suffering, but no dangerous symptoms, recovered, the cholera spirillum being isolated from the discharges at various times during his illness. There seems to be no doubt that this was a case of true cholera, arising from some carelessness upon the victim's part in handling the cultures with which he had to deal in the laboratory, for there were no cases of cholera in Berlin at the time, nor had there been for a long time previous.

The famous experiments of Pettenkofer and his pupils and similar experiments by Metschnikoff, in which cultures of cholera spirilla were deliberately swallowed, do not militate against the etiological importance of that spirillum. These experimenters suffered from symptoms similar to those observed in the milder forms of epidemic cholera, and the dejecta were similar in character and contained the spirilla in like numbers.

The entrance of the spirilla is undoubtedly effected by means of the gastro-intestinal tract, and there has not been a particle of evidence from experimental work to favor the theory of Pettenkofer that it may enter from the air and through the respiratory organs.

The acidity of the gastric juice is extremely unfavorable to the growth of the organism, and this explains the liability of the persons with functional or organic disease of the stomach to attacks of the disease, for in these instances the reaction of the gastric juice is altered or modified so as to allow the spirillum to pass this point of danger and reach the intestine, where there are more favorable conditions for its development. Diluted hydrochloric acid (0.05 per cent.) is said to kill the spirillum in six minutes. In the presence of pepsin 0.019 per cent. of acid suffices. Water, taken on an empty stomach, excites very little acid secretion—in fifteen minutes from 0.011 to 0.03 per cent. These quantities are entirely too small to prevent the passage of the organism.

Nicati and Rietsch, and Van Ermengen determined the toxicity of cultures of this organism when they had been deprived of the bacteria by filtration or when the bacteria had been killed by heating. In 1885 Nicati and Rietsch, by treating similar cultures with alcohol, succeeded in extracting a substance that killed guinea-pigs and rabbits, with the production of cramps and a lowering of temperature. Brieger studied the various chemical bodies that appeared in the cultures of the cholera spirillum; among the number there were convulsivants, methyl guanidin and a base, $C_3H_8N_2$, a febricant poison, and compounds that produced inflammation and necrosis. More recently, Brieger and Fraenkel have isolated a tox-albumin, and Petri has determined the presence of a less active substance, toxopeptine.

Hueppe and Scholl have perhaps made as important researches as any in their work upon cultures that have been deprived of free access of oxygen. From such cultures they succeeded in obtaining a [illegible]in that in a dose of 5 c.c., killed guinea-pigs in forty minutes, the animal presenting paralytic symptoms after ten minutes and convulsions after a quarter of an hour. This is a more active poison than was obtained before and was got in larger quantities; an egg after inoculation with a pure culture produced at the end of eighteen days enough to cause the death of ten guinea-pigs. The importance of this is seen when it is remembered that the spirilla are deprived of the access of oxygen when they are developing in the human intestine, and according to these experiments are therefore under the most favorable conditions for the development of this particular toxin.

Numerous experiments have shown that fluid artificial media do not usually become very toxic when cholera spirilla are grown in them. If they be filtered before the vibrios have died off to any considerable extent the filtrate is not highly toxic, while the residue, consisting largely of the bacteria themselves, is toxic in very much greater degree, even if heated sufficiently to kill the bacteria. That diffusible toxins may be produced in the animal body was shown by Metschnikoff, Roux, and Taurelli, who sealed cultures of cholera in collodium capsules which were introduced into the peritoneal cavities of animals with fatal results. The chemical nature of these various toxic substances is unknown.

A temperature of from 30° to 40° C. is the most favorable for the development of the cholera spirillum, but it will grow slowly at a temperature as low as 17° C. It ceases to grow at a temperature lower than this, but its vitality is not destroyed, and it grows well when the temperature is again raised; at −10° C. its vitality has been retained, but, on the other hand, heating to a temperature as low as 56° or 60° C. is sufficient to destroy its vitality in a short time.

Inasmuch as no true spore formation has been seen to occur in the development of this organism, it is not surprising that drying was shown, first by Koch, to destroy its vitality in a very short time—less than twenty-four hours. But conclusions drawn from his experiments may be misleading, for while this destruction of vitality by drying does occur in a very short time in the case of thin layers, it does not take place under less favorable conditions. This was shown by Kitasato, and by Berkholtz, who saw the vitality retained, the one for thirteen days and the other for thirty-eight, in experiments in which silk threads were used for holding the organism during their subjection to desiccation. It should be said, however, that these experiments were conducted in a desiccator, which did not permit the free access of oxygen to the bacteria, and it is undoubtedly the case that this agent is as important as any in the production of the result that it was desired to obtain. On the other hand, desiccation was probably more complete than would usually be the case under more natural conditions.

The organism has been found in ordinary drinking-water by Koch in one of the tanks in India, in the neighborhood of which an epidemic of cholera had broken out. It does not live long in distilled water, however, as shown by Meade Bolton, Wolfhügel and Riedel, and others. Strauss and Dubarry found that it lived for fourteen days in one case, and Kraus, for two days only. Other observers have not seen it retain its vitality for anything like so long a time. In ordinary sterilized water it lives longer, according to the experiments of Wolfhügel and Riedel, as well as Pfeiffer, who found that it existed for seven, nine, and twelve months, while Hochstetter lengthened this time to three hundred and ninety-two days. And more recently viability has been observed after nearly two and a half years. Its vitality appears to be shorter again in non-sterilized water. Strauss and Dubarry found it to be thirty days in one specimen, and thirty-nine in another; while a mixture of other bacteria shortens the time still more. This latter point is one of great importance and has been studied by many experimenters. Koch determined that the organisms ceased to live in ordinary drinking-water at the end of six or seven days, and that after twenty-four hours' contact with sewer water they appeared to be dead;

while Schiller, on the other hand, found that they retained their vitality in the same medium for fourteen days. Petri, in an effort to find out how long they lived in the intestine after burial, was able to demonstrate them in cultures at the end of nineteen days. Certain foods may be of great importance in transmitting the organism, as in the case of milk, in which it grows with great energy and without producing the least visible alteration; it has been shown that it will live for at least four days in milk and forty-eight in butter.

Most of these experiments were conducted with the idea that this organism is an aërobic one, but Hueppe has shown that it is also anaërobic, and that grown under these conditions the spirillum is possessed of a greater virulence, but it is also easier of destruction. As suggested by Proust, this may explain the comparative rarity of *immediate* infection. The bacterium coming from the intestine as an anaërobic organism is possessed of feeble resisting powers and is therefore easily destroyed, and it is only after it has taken on the conditions of aërobic growth that are furnished it in the medium in which it develops outside of the body that it finds itself possessed of the power of resistance sufficient to enable it again to enter the human body. Such observations are of especial interest in connection with the theory of Pettenkofer (*vide supra*), as seeming to show that his idea of the influence of locality is exact, in so far as this influence is exerted in changing the anaërobic to aërobic conditions of growth and effecting an adaptation of the organism to this change.

According to Koch, solutions of 1 in 400 of carbolic acid, 1 in 2,500 of sulphate of copper, and 1 in 10,000 of corrosive sublimate are sufficient for the arrest of the development of the spirillum of Asiatic cholera. Esmarch and Eisenberg show that creolin will destroy it more quickly than carbolic acid in solutions of the strength of from 1 in 1,000, or 1 in 2,000. Liborius, Kitasato, and Pfuhl have shown the active effect of freshly prepared milk of lime, while Hueppe and Loewenthal convinced themselves of the important prophylactic and therapeutic value of salol in the management of cholera.

TREATMENT.—*Inoculation Against Cholera.*—The first efforts to confer active or passive immunity to cholera in the human subject were made by Ferran, a Spanish physician (Report to the Academy in Barcelona, July 16th, 1884), who attempted to immunize more than twenty-five thousand people during 1885, when cholera was epidemic in Spain. His method consisted in the subcutaneous injection of increasing amounts of virulent cultures of the cholera vibrio, five or six days being allowed to elapse between successive injections. Three such injections were regarded by him as fully protective against the disease. He also employed injections of blood from those who had recovered from cholera to protect others from attacks of the malady. His enthusiastic claims for the efficiency of these prophylactic measures were discredited by other observers, and there appears to be no doubt that his methods were faulty. The purity of his cultures is open to question and his claims were exaggerated. But his conceptions were the same as those which subsequently led to more careful and promising work in this direction, and the credit of priority belongs to him.

Since these early attempts of Ferran, which were based upon studies of the immunization of guinea-pigs at a time when proper methods had not been elaborated, numerous investigators have experimented on animals in this direction and have obtained results which throw considerable light on the character of the immunity that can be conferred upon animals, and presumably upon man.

One of the difficulties encountered in this work is due to the fact that the lower animals do not respond to cholera infections so as to present a well-defined disease comparable to human cholera. Fatal results may follow intravenous, subcutaneous, or intraperitoneal inoculations with cholera cultures, and also after the introduction of cultures into the stomach. But special preparation of the animals for this last mode of inoculation is usually necessary. The procedure for this purpose, devised by Koch for guinea-pigs, was the neutralization of the stomach contents with sodium carbonate, and the checking of intestinal peristalsis with a subcutaneous injection of tincture of opium. If, after this preparation, the animals receive cultures of the cholera vibrio, introduced through a stomach tube, they develop symptoms which bear some resemblance to the algid stage of cholera. The temperature falls, the skin becomes cyanotic, and great muscular weakness is manifested by inability to walk or stand. Occasional muscular spasms are frequently observed and the animals die after several hours. These symptoms do not develop immediately after the inoculation, and there is evidently a very considerable multiplication of the vibrios in the intestine. At autopsy the serous coat of the intestine is injected, the intestinal wall is swollen, and a serous fluid containing desquamated epithelium fills the bowel. There are usually no evacuations, though occasionally a thin serous fluid escapes from the anus.

While these manifestations bear some resemblance to the algid stage of human cholera, the results of such inoculations cannot be regarded as satisfactory reproductions of this disease. In 1893 Metschnikoff published observations showing that young, suckling rabbits might be inoculated with minute quantities of cholera vibrios placed in the mouth, and that they then developed a fatal disease more closely resembling human cholera than that obtained in guinea-pigs by Koch. This was subsequently shown to be the case when very young kittens or puppies were employed. We shall have occasion to refer to these experiments again.

Experiments with a view of determining the possibilities of immunizing against cholera have been very numerous. Most of the observations have been made on guinea-pigs, though other animals have also been employed. It has not been difficult to attain positive results in many different ways. Intraperitoneal, subcutaneous, or even intravenous inoculations with non-lethal amounts of living cultures of cholera vibrios is followed within a few days by a species of immunity manifested by bactericidal or bacteriolytic properties of the serum of the animal. Such animals will then survive inoculations with virulent cultures in amounts which considerably exceed those regularly fatal to normal animals. Similar results may be obtained by the use of dead cultures, whether the vibrios have been killed by heat or by the addition of germicides. Such animals also are immune against inoculation with virulent cultures in considerable amount. This immunity, whether caused by living or by dead cultures, protects the animals against inoculations into the blood, peritoneum, or beneath the skin; but appears to have little if any effect upon the course of the disease when cultures are introduced into the mouth or stomach. This fact was strikingly manifest in experiments in very young animals, which, as stated above, readily acquire a form of cholera when very small amounts of cultures are introduced into the mouth. Moreover, very large amounts of cholera cultures introduced into the blood or peritoneal cavity cause death in immunized animals in spite of their protection against moderate lethal doses. Large doses of dead cultures also cause death. A fact worthy of note is that filtered recent cultures of the cholera vibrio are neither very toxic nor useful for immunization.

The results of the experiments mentioned above lead to the inference that the introduction into the body of non-lethal quantities of the vibrio calls forth the production of anti-bodies that are destructive to the vibrio if they are brought into contact with it, but that they are not capable of neutralizing toxic substances that appear to be closely associated with the bodies of these micro-organisms if not actually a part of their structure. The immunity obtained is due to bacteriolysis and not to antitoxins. We may, therefore, fatally poison an immune animal with cholera cultures though it be capable of destroying a limited number of cholera vibrios which are brought into its tissue fluids.

It has been shown that the blood and serum from patients who have recovered from attacks of cholera also contain these or similar bacteriolytic substances, but there appears to be no antitoxic substance in these fluids.

These bacteriolytic anti-bodies do not exist to an appreciable extent in the blood of convalescents immediately upon recovery, but are distinctly active about three weeks after the attack, then gradually accumulate or increase in potency until a maximal efficiency is reached between the fourth and sixth weeks. At this time 0.01 c.c. of the blood may be enough to protect a guinea-pig from the effects of an otherwise fatal intraperitoneal infection with cholera. After the sixth week the bacteriolytic value of the blood gradually declines and is lost after about three months.

To emphasize still further the character of this immunity, experiments may be cited which show that animals which have been inoculated with cholera vibrios in amounts ordinarily sufficient to kill, may be saved if they receive injections of serum from immunized animals within from one-half to two hours after the inoculation, before symptoms referable to intoxication have developed. When these symptoms have declared themselves the treatment is without avail, *i.e.*, if the disease can be checked by destroying the vibrios already in the system, the immune serum will protect; but if there is already in the body a dose of toxic substances sufficient to kill, the immune serum is powerless to neutralize them. These toxic substances appear to be present in lethal quantities in the majority of cases, as soon as symptoms of disease become manifest.

A question of great practical importance is whether these protective, bacteriolytic anti-bodies which are present in the blood and lymph can pass into the digestive tract and act upon cholera vibrios present in the intestinal contents. Experiments upon animals, already cited, appear to answer this question in the negative, but it is doubtful whether these results can be directly applied to man. If Ferran's claims are justified by the facts, such direct application of animal experiments cannot be made; for an active immunity caused by subcutaneous injections of cholera vibrios would appear to protect against infection by way of the mouth in human subjects, though they failed to do so in animals. It was the belief that such was the case that induced Haffkine to undertake the immunization against cholera by a method essentially similar in principle to that employed by Ferran, but safeguarded by a more highly developed technique.

Haffkine experimented with his method of immunization in India, aided by the Government, and between 1893 and 1895 had subjected about forty thousand people to his prophylactic treatment. This consisted in the subcutaneous injection of living cultures of the cholera spirillum of definite and known virulence. The first injection was made with a culture of moderate virulence, attenuated by long artificial cultivation and taken by him to India from the European laboratories.

These injections were made only after a microscopical examination of a stained smear had failed to reveal contamination of the culture and revealed well-formed, apparently normal cholera vibrios. The injections were made under strictly aseptic conditions. During the first two hours after the injection there were no appreciable effects either locally or constitutionally. Between the third and twelfth hours there was a gradually developing tenderness at the point of inoculation with general malaise and fever. In normal cases the fever reached 101° F., but would sometimes reach 104° when the susceptibility of the patient was great. The amount of culture injected depended upon the age of the patient; for an adult man the amount being about 1 c.c. From the twelfth to the thirty-sixth hour after the inoculation the general symptoms gradually but completely vanished and a painful induration at the point of inoculation developed. This also subsided in the course of a few days. No digestive disturbance was occasioned by the inoculation, and no change of diet or occupation was necessary.

The second inoculation was made about five days after the first. For this purpose a highly virulent culture, kept active by passage through susceptible animals, was employed, the dosage being determined by the reaction obtained after the first injection. The effects of this inoculation were essentially the same as those obtained after the first, but were usually less pronounced. The immunizing action was believed to be complete six days after the first inoculation. Up to 1896 over one hundred thousand people are said to have received this treatment.

The results of this treatment, which was purely preventive, not curative, are reported as being very promising. Several of those so treated contracted cholera shortly after the first injection, showing that its protective action was not immediate. Haffkine believed that the full protective action was attained in about twenty days. Comparative statistics, when of a given group about half were inoculated, were greatly in favor of the value of the method. The protection was not lasting, however, and seems to have gradually passed away, some twelve months being the probable limit of its efficiency. The protection is not absolute, and the mortality among those who have been inoculated and yet acquired the disease is but slightly less than among the uninoculated. About one-nineteenth as many cases occurred among the inoculated and about one-seventeenth as many deaths. Of late years this method appears to have fallen into disuse. This is not surprising when the difficulty of inoculating a whole population, the evanescent character of the protection, and the uncertainty of its absolute value are considered.

Upon theoretical grounds, as already stated, but little can be expected from a bacteriolytic serum injected beneath the skin in human cholera; for the vibrios are situated in the intestinal contents and the crypts of the intestinal mucosa.* To be effective the protective constituents of the serum must come in contact with the bacteria they are to destroy. It appears doubtful whether these elements enter the intestinal lumen when present in the blood. A serum which had antitoxic properties should be much more efficient. Pfeiffer has shown that the most active toxic substances produced by the cholera vibrio are intimately connected with the bodies of the organisms when the latter are grown in artificial media. In 1896 Metschnikoff, Roux, and Taurelli-Salimbeni made experiments with a view of demonstrating that soluble toxins might be obtained from the cholera vibrio as a species of secretion. They obtained a highly poisonous toxin, not destroyed by boiling, of which one-fourth of a cubic centimetre killed a guinea-pig weighing 300 gm. in eighteen hours. They also showed that it was possible to obtain an antitoxic serum by immunizing animals with this toxin. But this serum failed to cure young animals infected by the mouth with cholera vibrios. As yet, therefore, there is no known serum therapy for cholera.

In the absence of a specific antitoxic or other remedy for cholera, recourse must be had to measures directed against morbid conditions as they arise.

A very great number of remedies have been employed with a view of destroying the cholera spirilla in the intestinal tract, or, at least, of inhibiting their multiplication. Among these remedies are: chlorine water, mercuric salts, salts of copper, iodine, iodoform, creosote, creolin, cresol, resorcin, thymol, pyoktanin, benzoic acid, salicylic acid and its salts, salol, tribromsalol, tribromphenol, bismuth, benzoyl-acetyl peroxide, etc. It cannot be said that the clinical evidence in favor of any of these remedies is strong, and upon theoretical grounds their utility is very doubtful since the great dilution they suffer in the intestinal tract must render them almost inert. The same appears true of the proposed treatment with mineral acids in eight- to ten-drop doses, diluted with water.

We have already seen that during epidemics of cholera mild cases of this disease are of not infrequent occurrence. These cases are indistinguishable in many instances from attacks of simple diarrhœa due to intestinal irritation or indigestion, though frequently unaccompanied by pain. The only safe rule at such times is to regard all cases of diarrhœa as choleraic and as the possible beginning of a serious attack. The patient must be put to bed and isolated. The dejecta should be regarded as likely to contain the cholera spirilla, and carefully disinfected before being disposed of. A warm bath, with warm compresses on the abdomen, has been recommended. The diet should be restricted to fluids, previously boiled. Thirst may be relieved with boiled or carbonated (not alkaline) water. There are differences of opinion regarding the measures appropriate to the treatment of the diarrhœa. The usual practice is to employ some preparation of opium to check the discharges. The tincture given in small, frequently repeated doses has given good results. As it is important to allay all intestinal irritation it must be a matter of judgment in each individual case whether it be wiser to endeavor at once to check the diarrhœa or whether a freer evacuation of the bowels to discharge any irritating contents should be attempted. For the latter purpose calomel in repeated moderate doses, given until the stools become greenish, has a good reputation. Castor oil, emulsified with mucilage of acacia, peppermint water, and syrup, has also been employed. It is thought that calomel is partially converted into mercuric chloride in the intestine, and that it thus exerts some antiseptic action; but to what extent this is true is not known. As an antiseptic sodium sulphocarbolate, in fifteen- to twenty-grain doses for children and thirty-grain doses for adults, repeated every three or four hours, has been used with asserted beneficial effects. To check the diarrhœa, besides opium, astringents have been used and recommended, and to relieve pain the compound tincture of camphor has been employed. The prevalent opinion, however, is that opium fulfils the requirements better than other drugs, and that rest, warmth, and an appropriate diet are of the utmost importance. Tea and moderate stimulation with brandy may be used according to the indications.

---

* The efficacy of the bacteriolytic serum when administered by mouth or in enemata does not appear to have been tested. It would be worthy of trial.

Should the symptoms persist and vomiting set in notwithstanding the treatment indicated above, the copious enemata of tannic acid, recommended by Cantani, may be resorted to.

Long before the epidemic of 1866 Dr. Murray, in India, had recommended the half-hourly injection of a pint of a weak solution of common salt and carbonate of sodium into the rectum at a temperature of 120° F., and is said to have obtained very striking results. Similar means were employed by Sansom (*The Practitioner*, November, 1892), in 1866. Cantani advises the addition of tannin to the hot water. From eighty to three hundred and twenty grains are dissolved in three pints or a quart of water or chamomile infusion at a temperature of 102° to 105° F., and twenty drops of laudanum and an ounce or an ounce and a half of gum acacia are added. Instead of tannin, thymol in solution of hot water (1 in 1,000) has been recommended by other authorities. In the recommendations of the Royal College of Physicians (1892), benzoate of sodium, two drachms to a quart of water, has been suggested as an alternative to the tannic acid. In every case the injection should be made with much gentleness. The best position of the patient is that on the back with the hips well raised and the legs well drawn up as for lithotomy. The reservoir douche enema should be used and not the ordinary pump. There is much room for doubt as to whether the addition of any medicament to the hot water is of any special value, the favorable results being due probably to the clearing away of irritant and offensive *débris*, to the absorption of fluid from the intestinal surface, and to the relaxation of the arterial spasm by the hot and moist application; but up to the present time the use of tannic acid persists and is recommended. If more than two quarts are injected, a weaker solution should be employed. These enemata may be repeated several times in twenty-four hours. As shown by Cantani, the hot saline solution may pass through the ileo-cæcal valve into the small intestine.

If signs of improvement do not soon follow the procedure described above, and the algid stage of the disease supervenes, recourse should be had to the second method, of introducing fluid recommended by Cantani and called by him "hypodermoclysis," and consisting in the injection of a hot saline solution into the subcutaneous tissue. About one drachm of common salt is dissolved in a quart of distilled water at a temperature of 100° to 105° F. The apparatus for this should consist of a glass funnel with a long rubber tube attached to a hypodermic needle of fairly large calibre. The needle is introduced in the gluteal, interscapular, lumbar, or iliocostal region, the funnel being held at about the level of the patient, and the needle pushed so far in that it may be moved freely in the subcutaneous tissue. The reservoir is then elevated slowly so that the fluid runs into the tissue by the force of gravity and its distribution is aided by the manipulation of the fingers. When about half of the fluid has been introduced the needle is removed and the remainder is injected in another place. The method seems to be rational and is supported by strong evidence by Cantani, who has made extensive use of it. It was also extensively employed in the Hamburg epidemic. It is easier of application than the older method of intravenous injection that has been employed for many years, and it seems to be attended with better permanent results. Either or both of these methods must be employed earlier than is usually the case, and before the actual symptoms of death have made their appearance; to wait too long is to throw away all chances of success. The amelioration of the symptoms is usually very striking and prompt, due to the introduction of fluid and warmth; but improvement is frequently of short duration. The procedure may be repeated if the indications for it return; but experience has led to the belief that three or four injections of a quart or more are all that are likely to be beneficial.

Rest and quiet being of the greatest importance, owing to the exhausting nature of the disease, it must be a matter of judgment to what extent active measures to combat the conditions as they arise are wise. The patient should be kept as quiet as is compatible with proper care.

During collapse the condition of the circulation excites most solicitude. When the pulse at the wrist is lost and cyanosis appears, the most efficient remedy is the injection of fluid either intravenously or beneath the skin, as already described. Where the loss of fluid is less pronounced, careful stimulation with cold champagne or brandy and water may be tolerated by the stomach. Subcutaneous injections of ether or nitroglycerin, if used with care and not contraindicated by the condition of the patient, may give good results. Inhalations of small doses of amyl nitrite may also prove beneficial. In the early stages of the disease opium may be used to relieve pain, for it also tends to check the diarrhœa. But in the later stages, when there is danger of collapse, this drug should be avoided. Pain must then be relieved by other means, such as hot applications, moderate counter-irritation, inhalations of chloroform, or subcutaneous injections of camphor rubbed up with olive oil in the proportion of one part of camphor to nine parts of oil sterilized by heat. Gentle massage may give relief from pain, but is likely to disturb the patient more than is wise.

Thirst can best be relieved by ice held in the mouth, cold carbonated water, or nourishing fluids given in small amounts and at frequent intervals.

To prevent loss of heat, the patient should be kept in a warm room, the skin should be kept as dry as possible without disturbing the patient, and he should have dry heat applied by means of hot-water bottles or warm bricks; or the temperature may be maintained by hot compresses.

After recovery from the severe stage of the disease the treatment must follow the indications as they arise. Particular attention must be given to the diet, relapses being frequently traceable to neglect in this direction.

Prophylaxis.—Two principles govern the measures which should be taken to avoid cholera. The first looks to the exclusion of living cholera spirilla from the gastro-intestinal tract; the second refers to preserving any natural resistance, particularly on the part of the intestine, to injury due to the presence of that organism in the intestinal contents. It is believed that the toxins produced by the cholera spirillum are not absorbed through intact intestinal epithelium, but gain entrace to the circulation only after the epithelium has become damaged, necrosed, or desquamated. Therefore all dietary indiscretions which might cause intestinal irritation are to be avoided. Over-fatigue and exposure to cold are to be carefully guarded against. But it appears wise not suddenly to change the ordinary mode of life, but simply to follow the usual habits in a temperate manner. The free use of alcohol appears to be extremely dangerous. Those addicted to its use are particularly susceptible, and when attacked by the disease the prognosis is bad in people of intemperate habits. Care in the character of the food is important. All articles which might carry infection should be avoided entirely, or partaken of only after being cooked. This is especially the case with water and milk, which should be heated to the boiling point. Prolonged boiling is not necessary, but to insure the death of the spirillum it is safest actually to boil liquid articles of food. It has been recommended to take acid drinks, such as very weak hydrochloric acid, as a prophylactic measure, but it seems doubtful whether this is a wise measure, in view of the danger to the digestion if sufficient acid be taken to act as an effective agent in killing the spirillum. Particular care should be exercised against infection by those attending cases of cholera. They should disinfect the hands immediately after they have come in contact with the dejecta or vomitus from the patient. A two- or three-per-cent. solution of carbolic acid, 1 in 1,000 solution of mercuric chloride, or a solution of "chloride of lime" may be used for this purpose. It is possible that peroxide of hydrogen might find useful application for this purpose and in cleansing the patient, particularly for rinsing the mouth; its freedom from toxic properties and odor and its acid reaction particularly commending it.

The public measures for preventing the spread of cholera must be directed toward the destruction of the spirillum, and, when that is not possible, the checking of its dissemination. Each case that occurs must be regarded as a possible centre from which other cases may arise. The patient must, therefore, be isolated and the utmost care taken to destroy all the spirilla in the dejecta and vomitus, on the bedding and clothing, and on the hands or persons of those attending him. As the patient must be kept as quiet as possible, the evacuations must be received in a bed-pan and disinfected before being disposed of. For this purpose milk of lime has been found very efficacious. This may be prepared as follows. One volume of quicklime, which must not be air-slaked, is placed in a large vessel containing an equal volume of water. This is gradually absorbed by the lime, which then falls to powder. Three volumes of water are then added and the whole is stirred to a thin creamy fluid. Of this equal parts should be added to the dejecta and the mixture allowed to stand for an hour, when disinfection may be considered complete. Fresh "chloride of lime" may also be used, a large heaping tablespoonful of the powder being added to each quart of the evacuations and thoroughly mixed with them. In half an hour the mixture may be regarded as harmless. The hands of the attendants should be disinfected immediately after coming in contact with the patient. The supernatant fluid obtained by mixing 2 parts of fresh "chloride of lime" and 100 parts of water, shaking, and allowing the sediment to settle, may be used, or a two- to three-per-cent. solution of carbolic acid, or 1 in 2,000 corrosive sublimate. These solutions may also be used to cleanse the patient. Sheets and linen may be soaked in 1 in 1,000 solution of corrosive sublimate, the above solution of carbolic acid, or in a three-per-cent. solution of green or soft (potash) soap, with or without the addition of five per cent. of crude carbolic acid. The fluid must completely cover the articles. The simple soap solution must act for twenty-four hours; the carbolized soap solution will disinfect within twelve hours. Weak formalin, two per cent., may also be used where its odor and irritating properties are unobjectionable. In emergencies, where facilities for carrying on such disinfection cannot be obtained, boiling or burning may be employed to destroy the spirilla.

The bodies of the dead should be disinfected or wrapped in a sheet wet with 1 in 1,000 corrosive sublimate solution, and placed in a tight coffin upon a layer of some absorbent material. The sick-room must be disinfected with sulphurous acid or formaldehyde, or thoroughly washed with 1 in 1,000 corrosive sublimate, and be well aired and dried out before being again occupied.

Harold C. Ernst.
Revised by *Edward K. Dunham.*

BACTERIOLOGICAL TECHNIQUE.—The methods for the artificial cultivation of bacteria are of fundamental importance in bacteriology, and for that reason deserve very careful consideration. Nutrient media of various kinds are used, but the three most commonly employed are bouillon, gelatin, and agar. These in turn may be variously modified as the needs of the work may require. In addition, other media are used, such as blood, serum, exudates, eggs, urine, milk, potatoes, and the like. These will be severally considered.

BOUILLON.—To prepare beef tea, or bouillon as it is called, 500 gm. of lean, chopped beef (Hamburger steak) are placed in a suitable enamelled vessel or in a one-and-a-half-litre flask and 1,000 c.c. of ordinary tap water are added, and the whole is thoroughly mixed. This may now be set aside in an ice-box for twenty-four hours so as to bring the soluble constituents into solution; or, what is preferable, it may be placed in a water-bath and warmed at a temperature not exceeding 60° C. for an hour. In this way the nutrient substances are dissolved out and much time is saved. It is not desirable at this point to heat the fluid above the temperature given, inasmuch as that would lead to the coagulation of the albuminous constituents, which, if they are allowed to remain in solution, will facilitate the subsequent clarification of the medium. When the digestion is completed, whether carried out at a low temperature or in the water-bath, the liquid is strained through well-washed, starch-free muslin, or the juice may be expressed by means of a meat press. The liquid thus obtained is of a dark red appearance, due to the presence of hæmoglobin.

One thousand cubic centimetres of the meat extract are then placed in a clean flask or vessel, and 10 gm. of dry, powdered peptone (Witte's) and 5 gm. of common salt are added and the whole is then warmed at about 55° to 60° C. till the peptone has dissolved. The next step is to render the medium suitably alkaline, since bacteria as a rule require a slightly alkaline soil. This manipulation requires special care, for, if improperly done, the finished product may be cloudy, or may even have a deposit, or may even be unfit for the growth of bacteria. The clouding and the formation of a precipitate can be avoided by boiling the meat extract after adding just enough alkali to neutralize the fluid. For this purpose 5 c.c. of *normal* sodium hydrate (four-per-cent. solution) are added to the litre of meat extract. This amount is usually sufficient to make the extract neutral to litmus. The liquid is then heated in a boiling water-bath or over a free flame for about fifteen minutes, after which it is filtered through a moist plaited filter and allowed to cool to about 50° C. As stated, bacteria thrive best when the medium is slightly alkaline. Hence 10 c.c. of the normal sodium hydrate are now added to impart the desired alkalinity, after which the liquid is again boiled for twenty to thirty minutes, and finally filtered through moist paper.

Inasmuch as considerable water is usually lost by vaporization during the preparation of the medium, it is advisable either to indicate the volume at the beginning of the operation by a suitable mark on the vessel, or, better, to take the weight of the fluid before and after heating. The difference in the volume or weight is finally made up by the addition of the corresponding amount of distilled water. The finished bouillon should make up to the original volume of meat extract, that is, 1,000 c.c.

The beef tea thus prepared is now filled into tubes or into flasks, as the case may be, and sterilized by steam. This process will be described later. It is hardly necessary to add that the bouillon after being tubed and sterilized should be perfectly clear, without a deposit, and should have a slight alkaline reaction.

For cultivating the gonococcus Thalmann recommends using the ordinary bouillon, to which has been added two-thirds to three-fourths of the amount of alkali necessary to make it neutral to phenolphthalein.

Sugar-free Bouillon.—The bouillon as just prepared always contains some sugar derived from the muscle tissue employed. For many purposes this sugar content is undesirable, and must be removed in some way. One procedure is to allow the meat extract to ferment at a low temperature, 10° to 15° C., for two days. Another is to place the meat extract at 87° C. for twenty-four hours. Neither one of these methods will give results which can be relied upon. The best procedure is to add to the meat extract a rich fluid culture of some acid-producing organism, such as Bacillus coli (Smith), or B. lactis aërogenes (Durham), and then set it aside to ferment at 87° C. for twenty-four hours or longer. The frothy liquid is then carefully neutralized by the addition of normal sodium hydrate, peptone and salt added, then boiled, cooled, and rendered alkaline according to the directions given under the preparation of bouillon. The sugar-free bouillon thus prepared does not contain indol, as might at first be supposed. It is preferable to the Dunham peptone solution mentioned below for testing for the presence of indol, since a good reaction is given in sixteen hours, whereas the cultures in Dunham's solution often require several days before giving a positive test.

Martin's Bouillon.—The thoroughly mixed meat suspension (500 gm. of chopped beef and 1,000 c.c. of water) is set aside at about 37° C. for twenty hours so as to destroy the sugar normally present. The liquid is then strained through well-washed muslin, and to 1,000 c.c. of the filtrate 5 gm. of common salt are added, after which the liquid is neutralized and finally rendered alkaline by the addition of 7 c.c. of normal alkali per litre of bouillon. Ordinary peptone is not added, inasmuch as it is likely to contain sugar. Instead. Martin adds to this bouillon an equal volume of a rich peptone solution made by digesting the stomach of a pig. This latter solution is prepared as follows: A pig's stomach is cleaned and cut up into small pieces, and to 200 gm. of this finely divided tissue 1,000 c.c. of water and 10 c.c. of concentrated hydrochloric acid are added and the mixture is set aside at 50° C. for about twelve hours. The digested fluid is then decanted through a filter of absorbent cotton and the strongly acid reaction is reduced by the addition of 25 c.c. of a sixteen-per-cent. solution of sodium hydrate. The liquid is then carefully neutralized, after which it is rendered alkaline by the addition of 7 c.c. of normal sodium hydrate per litre. The mixture of equal volumes of the sugar-free bouillon and the peptone solution is heated, filtered, and tubed or placed in flasks.

Peckham's Bouillon.—This is made by taking finely chopped beef, which must be as old as it can be obtained in order that it may be free from muscle sugar, and adding 225 gm. of it to 500 c.c. of water. The mixture is rendered slightly alkaline with sodium carbonate, after which it is placed in a water-bath at 40° C., and 4 gm. of trypsin are added. After digesting for an hour the fluid is again rendered alkaline with sodium carbonate. In from one to one and a half hours the digestion should be arrested, otherwise traces of indol may be detected. At the end of this period the mixture is boiled and strained through gauze and filtered cold through wet filter paper to remove the fat. Five grams of salt and enough water to make up to one litre are then added. The acidity of the clear straw-colored filtrate is then reduced to the desired point. The most suitable reaction for the development of colon and like bacilli is when the medium contains such an amount of free acid as to require from 20 to 80 c.c. per litre of a decinormal sodium-hydrate solution to bring it to a point neutral to phenolphthalein.

Artificial digestion of muscle tissue by means of pepsin and trypsin is resorted to in the preparation of Deycke's agar.

Dunham's Peptone Solution.—This is prepared by dissolving 10 gm. of Witte's peptone and 5 gm. of common salt in 1,000 c.c. of ordinary tap water. The solution is then tubed and sterilized by steam. This medium is used to detect the formation of indol by bacteria, but inasmuch as many organisms fail to grow in it and others require several days before giving a reaction, it has not been found to be as suitable as the sugar-free bouillon given above.

Glucose Bouillon.—This is used to test for acid and gas production. It is made by adding to the ordinary bouillon, or better to that which is sugar-free, one or two per cent. of glucose. The two-per-cent. solution is most commonly employed. The sterilization of sugar-containing media by steam requires special care to prevent oxidation of the carbohydrate present. As a rule the steaming should not exceed ten or fifteen minutes each day on three successive days.

Instead of glucose other carbohydrates may be added to the bouillon in one- or two-per-cent. concentration. Thus galactose, lactose, saccharose, maltose, dextrin, and the alcohol mannite are frequently used to differentiate between organisms which otherwise closely resemble each other.

Glycerin Bouillon.—This is especially used for cultivating the tubercle bacillus. It is made by adding five per cent. of glycerin to the ordinary bouillon. The mixture is then tubed and sterilized in the usual way.

Carbolic Bouillon.—This is made so as to contain 0.1 per cent. of carbolic acid. One gram of acid may be added to one litre of bouillon. The better procedure is to add 1 c.c. of a one-per-cent. carbolic acid to 9 c.c. of bouillon. It is advisable to incubate the tubes for several days so as to eliminate any possible contamination. The medium is useful for examining water for the colon bacillus, especially when the bacterial contents are very high. The presence of the antiseptic serves to check or prevent the growth of many organisms which would otherwise develop. It should be borne in mind that weak colon and typhoid bacilli are likewise restrained.

The tubes after inoculation with the water are incubated for twenty-four hours at 38° C., after which lactose litmus agar plates are made, which are then examined for red colonies. Of course all red colonies are not to be regarded without further study as the colon bacillus.

Parietti's Bouillon.—A mixture of carbolic acid and hydrochloric acid is first prepared by adding 4 c.c. of the latter to 100 c.c. of a five-per-cent. carbolic solution. This solution after standing a few days is added in portions of 0.1, 0.2, 0.3 c.c. to portions of 10 c.c. each of sterile bouillon.

Colored Bouillon.—Various coloring agents are added to the nutritive media in order to bring out the acid-producing or the reducing properties of bacteria. The substances which are most commonly used for this purpose are litmus, neutral red, saffranin, and sodium indigo sulphate. The first two are particularly useful, and are prepared the same as the corresponding agar or gelatin media, which see.

GELATIN.—The ordinary nutrient gelatin is really nothing more than bouillon to which ten per cent. of gelatin has been added so as to impart solidity with the additional advantage that the medium is transparent. The method of preparation is as follows: To 1,000 c.c. of the meat extract, prepared according to the directions given under bouillon, 100 gm. of the best sheet gelatin are added; likewise 10 gm. of Witte's peptone and 5 gm. of common salt. The whole is then warmed in a water-bath at 60° C. until the gelatin has passed into solution. The liquid is then neutralized and enough alkali added in excess so as to impart a suitable alkalinity. As ordinarily prepared the nutrient gelatin requires from 30 to 35 c.c. of normal alkali to effect neutralization. An additional 10 c.c. will give the desired alkalinity. Hence 40 c.c. of the normal alkali may be added at once and the liquid tested with litmus paper. If the liquid is not distinctly alkaline more of the reagent may be added until the desired alkalinity is obtained. The method of standardizing media by means of phenolphthalein will be given later.

When the proper amount of alkali has been added to the gelatin solution the latter is then placed in a water-bath, the water of which is then raised to the boiling temperature. The gelatin is kept immersed in the actively boiling water for three-quarters to one hour. The albuminous constituents of the meat extract coagulate in flakes, and at the same time clarify the liquid so that on subsequent filtration the gelatin will be perfectly clear. The gelatin is then filtered through a plaited filter, which should, however, be first warmed by passing through it several hundred cubic centimetres of boiling water. If the paper and funnel are sufficiently warmed in this way there is no likelihood of the gelatin solidifying on the filter. The filtered gelatin should be perfectly clear, should possess a slight alkaline reaction, and should solidify when cooled under running tap water. If it meets these requirements it is then filled into sterile tubes to a depth of one and a half to two inches, and the entire lot of tubes are then sterilized by steaming for a quarter of an hour on each of three consecutive days.

Whenever nutrient gelatin is mentioned in bacteriological work it is understood to be a ten-per-cent. solution. This medium melts at about 23° C. That is warm summer temperature, and for that reason it is sometimes advisable to add more gelatin to the preparation in order to make it more solid. A twelve- or even a fifteen-per-cent. solution of gelatin is used under these conditions. Again, at other times it is desirable to employ a gelatin which is relatively quite soft, and in that case a five- or eight-per-cent. solution may be made use of. Obviously the amount of alkali necessary to neutralize such media will vary from that required for the ordinary gelatin. The great value of the gelatin medium lies in the fact that it can be readily melted and again resolidified, and in its transparency. Moreover, many bacteria give rise to soluble ferments or enzymes which peptonize or liquefy the gelatin, whereas others are not able to do this. It becomes possible therefore to divide bacteria into two large groups, according as to whether they liquefy or do not liquefy gelatin.

Glucose Gelatin.—This is made by adding to the clear filtered gelatin, prepared as above, two per cent. of glucose. The material is then tubed and sterilized the same as ordinary gelatin. This medium is particularly useful for the cultivation of anaërobic bacteria.

Glucose Litmus Gelatin.—To the glucose gelatin a concentrated solution of litmus is added so as to impart to the medium a deep blue color. This is then tubed and sterilized. During the steaming of this medium the litmus is usually decolored, but on subsequent cooling the blue color returns. If such a medium is overheated in the process of sterilization the sugar will be altered, and as a result the color of the litmus will change to more or less of a red.

For special purposes other sugars may be added to the gelatin, as in the case of bouillon. A lactose litmus gelatin is very useful in differentiating various organisms. The amount added is usually one or two per cent.

Elsner's Medium.—The addition of gelatin to a potato extract, instead of to a meat infusion, was first resorted to by Holz. Elsner's medium is essentially Holz's potato gelatin, to which one per cent. of potassium iodide is added. It can be used to good advantage in differentiating between the typhoid and colon bacilli, but at the same time it should be remembered that it does not afford an absolute means of detecting the former organism. The method of preparation is as follows: 1,000 gm. of well-cleaned potatoes are cut up into lumps which are then mashed as fine as possible, which can be done best by passing the material through a fruit press. The finely mashed potatoes are then placed in a meat press and pressure is applied. In this way about 400 c.c. of a dark liquid is obtained from the kilogram of potatoes. The potato juice is then set aside in an ice chest overnight, after which it is filtered through cotton. Ten per cent. of gelatin and one per cent. of potassium iodide are then added to the dark liquid, and the mixture is warmed at about 40° C. until the gelatin melts. Inasmuch as the reaction of this material varies considerably it is necessary now to determine the exact degree of acidity present, and then to reduce this by the addition of the proper amount of alkali, so that the resulting medium has an acidity such that it would require the addition of 20 c.c. of normal alkali per litre to make the solution neutral. The acidity of the gelatin is determined by titrating a portion, say 10 c.c., with decinormal sodium hydrate, using litmus paper as an indicator. If, for example, 10 c.c. require 3.2 c.c. of the decinormal alkali, it will be necessary to reduce the acidity by adding 1.2 c.c. of decinormal alkali, or better 0.12 c.c. of normal alkali for every 10 c.c. of gelatin made. When the proper degree of acidity has been imparted to the medium, the gelatin is then placed in a boiling water-bath for three-quarters of an hour until all the proteids have coagulated, after which it is filtered through paper, filled into sterile tubes, and sterilized by steaming for fifteen minutes on each of three consecutive days.

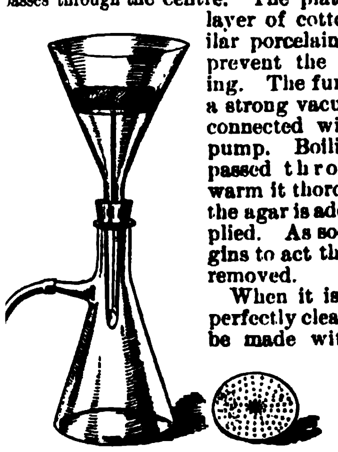
Fish Gelatin.—Five hundred grams of chopped fish are added to 1,000 c.c. of water, and the material is digested the same as given above for ordinary gelatin. To the strained liquid 100 gm. of gelatin, 40 gm. of salt, 5 gm. of glycerin, and 5 gm. of asparagin are added, and the mixture when perfectly fluid is rendered slightly alkaline. It is then heated, tubed, and sterilized as above. This medium is particularly useful for the growth of phosphorescing bacteria.

Nutrient Agar.—One drawback to the ordinary gelatin is that it cannot be used as a solid medium at temperatures above 23° C. This has led to the introduction of agar-agar as a stiffening agent. This substance is a seaweed gathered off the coast of Asia. It has no nutritive qualities of its own, and is unacted upon by bacteria. The preparation of nutrient agar is very simple. Ordinary bouillon is first made according to the directions already given. The agar may be obtained as a powder or in threads; in the latter case the agar is cut up into very small pieces, and 20 gm. (two per cent.) is then added to the litre of bouillon, which should be in a large flask, or, better, in an enamelled jar. The vessel and contents should then be weighed, after which the liquid should be gently boiled until the agar has completely dissolved. The vessel is now again weighed, and the difference between the two weights is made up by the addition of the proper amount of distilled water.

It is advisable to place the agar now in a water-bath at about 50° C. for several hours in order to allow the sediment to settle as much as possible. The filtration of a two-per-cent. agar is a very slow and tedious process even when carried out in a steam sterilizer. It is sufficient for practically all purposes to filter through a layer of cotton. The filtrate thus obtained is almost, if not entirely, clear, and whatever little sediment may be present does not in the least interfere with the usefulness of the medium.

The filter is prepared by placing a piece of ordinary cotton, about two inches square, in the angle of a large funnel, and then while it is held down by means of a glass rod, a litre or so of very hot water is passed through, once or twice, so as thoroughly to warm the funnel. Eventually the sedimented agar is carefully and slowly decanted on to the cotton filter. If desirable the agar can be filtered a second time. A very convenient arrangement for the rapid filtration of agar through cotton is shown in Fig. 5052. This consists essentially of

Witte's perforated porcelain plate, which is steadied n place in the funnel by means of a glass rod which asses through the centre. The plate is covered with a layer of cotton on which a similar porcelain plate is placed to prevent the cotton from floating. The funnel is inserted into a strong vacuum flask, which is connected with a Chapman air pump. Boiling water is first passed through the filter to warm it thoroughly, after which the agar is added and suction applied. As soon as the pump begins to act the top plate can be removed.

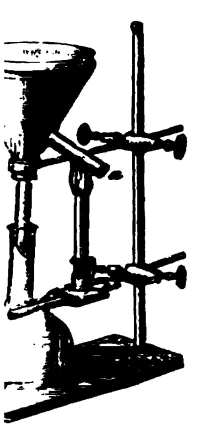


. 5052.—Filtration Through Cotton Over a Porcelain Plate. (Novy.)

When it is desired to make a perfectly clear medium it should be made with only one or one and a half per cent. of agar instead of two per cent., as given above. Such agar is softer and can be passed through a previously istened filter paper, especially if the funnel is placed steam sterilizer or in a funnel-shaped copper waterh, such as is shown in Figs. 5053 and 5054.

he filtered agar is then tubed and sterilized by steam one-half hour on each of three consecutive days, after ich it is kept in an upright position. When it is ded to make inclined or slant agar tubes, as many of e as are needed are melted in a water-bath and then ined so that the agar comes within an inch of the cotplug.

halmann's Agar.—Five hundred grams of meat are ed for one-quarter of an hour with 1,000 c.c. of disd water, after which the mass is made up to the origiweight and strained through muslin. One per cent. eptone and 0.5 per cent. of salt are then added, and liquid is boiled, after which it is again made up to the inal weight, cooled, and filtered. One and one-half cent. agar is then added and the weighed liquid is d in a concentrated salt-water bath for about threeters of an hour, after which it is again made up to riginal weight. Thirty cubic centimetres are then ted with normal sodium hydrate, using phenolphthalein as an indicator. The amount of alkali necessary to neutralize the entire amount of agar is ascertained and two-thirds of this quantity is then added, in portions and while shaking, to the agar. After heating fifteen minutes the material is filled into tubes.



3. — Double-Walled -Water Funnel.

According to Thalmann and others this medium is adapted for the cultivation of the gonococcus, especially for diagnostic purposes. A little of the pus is mixed with the water of condensation, and then by means of a wire, rod, or cotton swab the suspension is thoroughly spread over the surface of a series of inclined tubes or over Petri dishes. These when kept for twenty-four hours at 36°-37° show small, glistening colonies, are single or confluent and appear like highly ive drops.

medium is not suitable for subcultures, and Thalrecommends that the colonies be transplanted to bouillon. This is prepared by adding to some n two-thirds to three-fourths of the amount of alkali needed to neutralize the liquid. After heating and filtering, an equal volume of hog serum is added and the mixture tubed. The tubes are inclined and heated for one to two hours at 70° on the first and also on the second day, and for one hour at 100° on the third day. According to Wassermann hog serum is just as good as human serum for cultivating the gonococcus.

Glucose Agar.—This is made by adding to the filtered agar, or to so much of it as may be wanted, two per cent. of glucose. The medium is then tubed and sterilized in the ordinary way. It is used especially for the growth of yeasts and anaërobic bacteria. If desired it may be colored with litmus as in the case of gelatin.

Rothberger's Neutral-red Agar.—This can be made by adding to a 0.3 per-cent. glucose agar one per cent. of a saturated aqueous neutral red solution. The typhoid bacillus does not change the color or produce gas, whereas the colon discharges the red and leaves a fluorescing color. The inoculation can be made either by planting a shake culture or by making a stab culture, which can then be covered with a layer of agar to exclude air changes. The addition of neutral red to bouillon is of service in water examinations (Irons, Jordan).

Lactose Litmus Agar.—This medium was introduced by Wurtz, and is very useful in differentiating between the typhoid and colon bacilli. Acid formation in the case of the latter is indicated by a change in the reaction of the litmus. If this medium is made by the addition of two per cent. of lactose and litmus to the ordinary agar it will be found that even typhoid bacilli will give a slight acid reaction. This, however, is not due to the fermentation of the lactose, but to the small amounts of muscle sugar derived from the meat. It is therefore desirable that the agar for this purpose should be made out of sugar-free bouillon, which can be prepared according to the directions already given. Prolonged boiling of the agar must be avoided, inasmuch as the agar itself, since it is a complex carbohydrate, may split off some sugar.

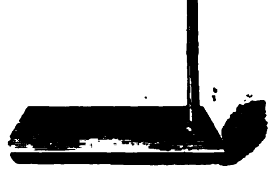


FIG. 5054.—Single-Wall Hot-Water Funnel with Ring Burner.

It is often preferable to make the plain lactose agar and to add to the tubed and sterilized medium, whenever needed, by means of a sterile pipette, a sterile litmus solution. Obviously other indicators, such as rosolic acid, neutral red, etc., may be added in the same way.

Glycerin Agar.—To the ordinary nutrient agar prepared as above, five per cent. of glycerin is added. The addition of glycerin serves to keep the surface of the medium moist, and at the same time imparts nutritive qualities to the agar. This medium is very valuable for the growth of diphtheria, glanders, pneumonia, and tubercle bacilli.

Mannite Agar.—Mannite, which like glycerin is a polyatomic alcohol, was first used by Norris and Hiss as a means of differentiating the typhoid from the dysentery bacillus. The latter organism does not give rise to acid production when grown on mannite media, whereas the typhoid bacillus does. The agar should be prepared from sugar-free bouillon, and to it one or two per cent. of mannite is then added. Litmus may be added to the bulk medium before it is tubed, or the sterile litmus solution may be added to the sterile tubed agar by means of a pipette whenever needed.

Pfeiffer's Blood Agar.—This is made by spreading over the surface of ordinary inclined agar a few drops of human blood. On the surface thus prepared he was able to cultivate the influenza bacillus. The blood from the lower animals can be used in like manner to good advantage.

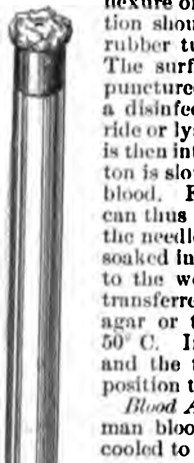

Fig. 5055.—Blood Pipette, Novy Form.

The human blood required for this and similar purposes can be drawn without difficulty by means of a sterile syringe from the large median veins just below the flexure of the elbow. The superficial circulation should first be diminished by means of a rubber tube tied about the middle of the arm. The surface of the skin over the vein to be punctured is thoroughly cleaned by means of a disinfecting solution, such as mercuric chloride or lysol. The needle of the sterile syringe is then introduced into the vein, and as the piston is slowly withdrawn the syringe fills with blood. Five or ten cubic centimetres of blood can thus be obtained in a few minutes. When the needle is withdrawn a compress of cotton, soaked in mercuric chloride, should be applied to the wound. The blood must be at once transferred to either the surface of inclined agar or to previously melted agar, cooled to 50° C. In the latter case it is mixed at once, and the tube is then set aside in an inclined position to solidify.

Blood Agar Mixture.—As just described human blood may be mixed with melted agar, cooled to 50° C., after which the mixture may be allowed to solidify in an inclined position. For diagnostic purposes this procedure has been utilized to detect the presence in the blood of typhoid bacilli, gonococci, and other organisms. Instead, however, of allowing the blood mixture to solidify in the tube it is poured out into a sterile Petri dish, and in this way a blood-agar plate is obtained, on which eventually colonies of the suspected organism may develop. The presence of a very few organisms can thus be detected in 1 or 2 c.c. of blood, which would not be possible by direct examination or by staining. The amount of blood which is added to the agar may be varied according to circumstances. Thus it may be one to four, one to two, or even one to one.

Blood from the lower animals can be drawn under strictly aseptic conditions into sterile Nuttall's blood pipettes, or into the modified form of Novy, shown in Fig. 5055. This can be easily made from test tubes of various sizes, according to the kind of animal to be bled. Thus a five-eighth by five-inch test tube may be used for bleeding a mouse or rat, while a one- by eight-inch tube would be used in the case of a rabbit. The bottom of the test tube and the end of a piece of glass tubing are softened in the flame of a blast lamp and then brought together. A narrow blast flame is then directed against the test tube about an inch from the bottom. On slow rotation in a horizontal position a thickened constriction results, and as soon as this is sufficiently thick the two ends are pushed apart slowly. A tapering capillary results, which is then sealed in the flame at a point about two inches from the tube proper. The tube is then plugged with cotton and sterilized by dry heat. When it is desired to prepare sterile defibrinated blood a drawn-out tube or a narrow glass rod is passed through the centre of the plug. By moving this about, after the blood has been received in the pipette, complete defibrination can be obtained, and that without any contamination from the outside.

In the case of the larger animals the blood is best drawn from the carotid artery. For this purpose the animal is anæsthetized and the artery exposed for about an inch. After the first incision it is advisable to avoid the use of cutting instruments, and instead to separate the tissues with the fingers. Pressure forceps are then applied at the distal end of the artery. Another pair are then applied about an inch below this point. A finger is then placed under the clamped portion of the artery and a very slight opening is made into the blood-vessel The blades of a very narrow pointed pair of forceps are then introduced into the opening, and, when distended, the tip of the sterile blood pipette can readily be introduced. Before this is done, however, the tip should be scratched with a file, then broken off, and the open end should be flamed for a moment to insure sterility and to round off the sharp edge. As soon as the pipette is in position the lower clamp is removed, when the blood rapidly rises in the tube. If defibrinated blood is desired, the blood should be stirred by an assistant. When serum is wanted this stirring is omitted. As soon as blood ceases to flow, the pipette is removed and the tip is sealed in the blast lamp.

Obviously in the case of small animals, such as the mouse or rat, this procedure is not applicable. The blood may be drawn up into a syringe from the artery. A much better way, however, which has been used for several years in the author's laboratory, is to take the blood directly from the heart into a small pipette of the same form as that used for the larger animals. For this purpose the thorax is opened, the heart is freed from the pericardium and raised by means of oval-tipped forceps. The end of the pipette is then introduced into the right ventricle. Suction may be applied to the end of the pipette in order to obtain the fullest possible yield.

Blood can be drawn from very large animals, such as the horse, by introducing a trocar into the jugular vein. This is the procedure which is followed in the preparation of antitoxins. The trocar is connected by means of a short rubber tube with a glass tube, which is inserted into the receiving cylinder. In this way several litres of blood can be drawn from the horse at each bleeding.

In ordinary laboratory work the blood which has been collected in the glass pipettes is then transferred to melted agar, which has been previously cooled in the water-bath to 50° C. The amount of blood which is added to each tube will vary with the purpose in view. It may be one part of defibrinated blood to ten of agar, or one to five, one to two, or one to one, as the case may be. Exceptionally two to one and three to one are used. The blood is then mixed with the agar and the tubes are set aside to solidify in an inclined position. The transfer of the blood to the tubes is best accomplished by means of a sterile drawn-out bulb pipette, such as is shown in Fig. 5084, *e*.

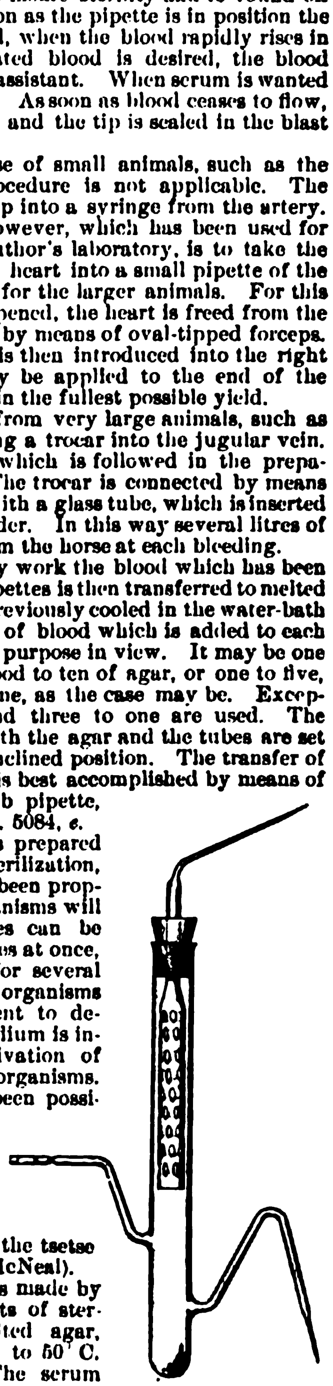

Fig. 5056.—Blood Pipette of Latapie.

The blood agar thus prepared requires no further sterilization, for if the operation has been properly carried out no organisms will be present. The tubes can be used for culture purposes at once, or they may be kept for several days to allow any organisms which might be present to develop. This blood medium is invaluable for the cultivation of various pathogenic organisms. On such media it has been possible, for example, to grow for the first time pathogenic protozoa—the trypanosoma Lewisi of rats and the trypanosoma Brucei, the cause of nagana or the tsetse fly disease (Novy and McNeal).

Serum Agar.—This is made by adding variable amounts of sterile serum to the melted agar, which has been cooled to 50° C. in the water-bath. The serum can be obtained by collecting the blood, as given above, in sterile pipettes. The blood is allowed to clot, and eventually when the serum has separated it can be drawn up into sterile bulb pipettes and transferred to the melted agar. The largest yield of serum is obtained by using the Latapie pipette shown in Fig 5056. This consists of an inner tube, which is freely perforated and the narrow, outer end of which is drawn out into a capillary for insertion into the blood-vessel. This tube is held in position within the outer one by means of a rubber stopper. The outer receiving tube, which is about an inch in diameter, is provided with two side tubes, one of which is drawn out and sealed while the other is plugged with cotton. The entire pipette is first sterilized by steaming in an autoclave. The tip of the inner tube is then broken, flamed, and inserted into the carotid artery of a rabbit or other animal. The blood should not fill the pipette beyond the inner tube. The tip is then sealed and the pipette is allowed to remain in a vertical position until the blood has firmly clotted. It is then inverted and the serum, as it is squeezed out of the clot, falls to the bottom. The purpose of the perforated inner tube is to allow more complete shrinking of the clot. The serum drains away at once from the clot, and is therefore perfectly clear. When it is desired to remove the serum the tip of the side tube is scratched with a file, then broken off, and the end is flamed to insure absence of bacteria. The tube is then inserted into a sterile test tube or flask and by blowing into the other side tube the serum is forced out. It can then be distributed to the agar tubes by means of a sterile bulb pipette. These are then allowed to solidify in an inclined position. As in the case of blood agar the medium prepared in this way is perfectly sterile, if the manipulation is properly carried out. Inasmuch as sterilization by heat is avoided, the proteid constituents of the serum remain in as near to the native condition as possible. Such serum agar makes an excellent medium for the pneumococcus and for other organisms. Obviously, serum-agar plates can be prepared, if it is so desired, in which case the melted and cooled agar is inoculated with the organism to be cultivated, after which the serum is added and mixed with the agar, which is then poured out into sterile Petri dishes.

Serum agar, made by adding human blood serum to melted agar, has been used for the cultivation of the gonococcus (Wertheimer). Ascitic or pleuritic fluid may also be added to agar in the proportion of one part of the fluid to two parts of the agar. Such agar is used especially for the cultivation of the gonococcus. The ascitic, pleuritic, or hydrocele fluids may be sterilized by fractional sterilization or by filtration through a Berkefeld filter under pressure.

Wassermann's Serum-Nutrose Agar.—This also has been found useful for cultivating the gonococcus. Five cubic centimetres of hog serum are added to 80 to 85 c.c. of water, 2–3 c.c. of glycerin, and 0.8–0.9 gm. of nutrose. Nutrose is a sodium phosphate casein compound, and when added to serum prevents coagulation on boiling. The solution is boiled for twenty minutes, after which it is added in equal parts to two per cent. peptone agar in test tubes. This mixture is then poured into Petri dishes. Nutrose has been used also in the preparation of the Drigulski-Conradi agar. Hog serum, which is said to be as good as human serum for cultivating the gonococcus, has been employed also by Thalmann.

Drigalski and Conradi Agar.—This is a meat-peptone-nutrose agar containing lactose, litmus, and crystal violet. The preparation is as follows: 1. A mixture of three pounds of meat and two litres of water is allowed to stand for twenty-four hours; the expressed meat juice is then boiled for one hour and filtered. To the filtrate are added 20 gm. of Witte's peptone, 20 gm. of nutrose, 10 gm. of sodium chloride, and the whole is boiled for one hour and filtered. To this filtrate 60 gm. of agar are added and the liquid is boiled for three hours, or one hour in an autoclave. It is then rendered alkaline to litmus paper, boiled half an hour, and filtered. 2. A solution of litmus is prepared according to Kubel-Tiemann as follows: The powdered commercial litmus is repeatedly extracted with hot distilled water. The liquid is acidulated with dilute acetic acid and evaporated to syrupy consistence on a water-bath. The thick fluid is then diluted by the gradual addition of ninety-per-cent. alcohol, transferred to a flask, and an excess of ninety-per-cent. alcohol is added. This precipitates the blue pigment, while the red dye and the potassium acetate remain in solution. The precipitate is filtered and washed with alcohol, then dissolved in distilled water, after which the solution is warmed and filtered. The filtrate is then added gradually to very dilute sulphuric acid (one or two drops of acid to 200 c.c. of water) till the color changes to a wine red. The concentrated blue is then added till the blue color is restored; 260 c.c. of this litmus solution are boiled for ten minutes, then 80 gm. of pure lactose are added, and the boiling is continued for fifteen minutes. 8. The hot litmus is added to the hot agar, mixed, and the reaction is made slightly alkaline; 4 c.c. of a hot sterile solution of ten-per-cent. anhydrous soda and 20 c.c. of a freshly prepared solution of 0.1 gm. of crystal violet in 100 c.c. of warm sterile water are then added, after which the material is filled into tubes or flasks. Excessive heating should be avoided, inasmuch as it alters the lactose. The crystal violet is intended to restrict the development of the unimportant bacteria.

The Drigalski-Conradi medium has been recommended for the isolation of the typhoid bacillus. For this purpose the fæces should be diluted with ten to twenty volumes of salt solution. The authors employ large plates, 15–20 cm. in diameter. The agar is poured into the dishes to a depth of at least 2 mm., and the cover is then kept off till the moisture has dried off the surface of the agar. By means of a 5 mm. glass rod, bent at right angles and previously dipped in the suspension, a series of streaks are made over a number of the dishes. The inoculated plates are then kept at 87° C. for twenty-four hours. The colon colonies are large, opaque, and red, while the typhoid are small, glassy, and resemble dew drops. The further identification of the suspected colony is made by applying the agglutination test and by growing in Rothberger's neutral red agar.

Gelatin Agar.—Several formulas have been proposed for the preparation of this medium. Each finds its special application. That of Capaldi was recommended for the isolation of the typhoid bacillus from fæces. It is made by dissolving 20 gm. of Witte's peptone, 10 gm. of gelatin, 10 gm. of glucose or of mannite, 5 gm. of sodium chloride, and 5 gm. of potassium chloride in 1,000 c.c. of water. The solution is filtered and two per cent. of agar is added and dissolved by boiling, after which it is rendered alkaline by the addition of 10 c.c. of normal alkali. The filtered solution is then tubed and sterilized by steaming.

Stoddart's medium is a gelatin agar which contains five per cent. of gelatin, one per cent. of peptone, and a half per cent. each of agar and of salt. A litre of meat extract is prepared in the usual way. In this 10 gm. of peptone and 5 gm. of salt are dissolved, and the solution is then divided into two parts. To one portion ten per cent. of gelatin is added, and when this has dissolved, the solution is neutralized and an excess of 10 c.c. of normal alkali per litre is added. The other half of the meat extract is likewise neutralized, and then 10 c.c. of the normal alkali are added per litre to impart the requisite reaction. The liquid is then measured or weighed, boiled, and filtered. Five grams of cut agar are added to the bouillon, which is then boiled until the agar dissolves. Distilled water is added to make up to the original volume or weight, after which the two liquids are combined and allowed to sediment. The entire product is finally filtered through cotton or, better, through paper. The medium is filled into tubes which are then steamed for fifteen minutes on each of three consecutive days. To use this medium, it is poured out into sterile Petri dishes, and when solidified the centre is touched with the organism to be tested. The typhoid bacillus, on account of its motility, spreads rapidly over the surface as an almost transparent growth, whereas that of the colon bacillus spreads less and is easily visible.

Guarnieri's gelatin agar is made in a somewhat similar manner. Three grams of powdered agar are emulsified with 50 c.c. of distilled water, and this is then added to a solution of 50 gm. of gelatin in 750 c.c. of meat extract. The whole is boiled till the agar has dissolved, when a solution of 25 gm. of Witte's peptone and 5 gm. of salt are added. The entire liquid, which now makes up to one litre, is then carefully neutralized with normal alkali, using litmus as an indicator. The medium is tubed and sterilized as usual. It has been used to advantage in the cultivation of the pneumococcus.

Weil's Meat-Potato Agar.—The potato juice is prepared as in the method of Holz or Elsner; 300 c.c. of this are added to 200 c.c. of slightly alkaline bouillon; 3.75 gm. of agar are then dissolved in the liquid, thus yielding a 0.75-per-cent. agar solution. The typhoid bacillus presents threaded colonies on this medium, the same as in Elsner, Hiss, and Piorkowski media.

Substitutes for the Meat Infusion.—In the preparation of the foregoing media a meat infusion served as the basis in each case. In special instances, but not as routine procedure, these media may be modified by using the commercial Liebig's beef extract in place of the meat infusion. The chief advantage lies in the fact that the beef extract can be kept always on hand. At the same time it must be remembered that media made up with such extract are by no means as nutritious as those made up with the meat infusion. The amount of Liebig's extract which is used varies with different workers. In general, from 1 to 3 gm. are added to one litre of water; 5 and even 10 gm. are also used. To this solution peptone and salt may be added in the usual amounts. The liquid when rendered alkaline and filtered constitutes a Liebig's extract bouillon. In the same way gelatin and agar media are prepared.

Peptone Substitutes.—Several compounds have been suggested as substitutes for Witte's peptone. In Martin's and Peckham's bouillon and in Deycke's agar this peptone is replaced by that which is formed by the digestion of the muscle tissue. In other media derivatives of albumen or casein are employed. Heyden's "Nährstoff" is a digested egg albuminate, while nutrose is a casein compound. The addition of lecithin, protogen, and hæmoglobin, etc., is made with the object of improving the nutritive qualities of the media.

Hiss' Tube Medium.—This is used as a means of testing for the typhoid bacillus. It is made by adding 5 gm. of Liebig's extract, 5 gm. of salt, and 5 gm. of agar to 1,000 c.c. of water. The mixture is then heated until the agar has dissolved, after which the water which is lost by evaporation is replaced and then eight per cent. gelatin is added. As soon as the gelatin has dissolved, the liquid is partially neutralized by the addition of normal alkali. The reaction is left acid, and to such an extent that it would require 15 c.c. of normal alkali per litre to make the solution neutral to phenolphthalein. The liquid is then cooled to 60° C. and cleared by the addition of the white of an egg stirred up in about 25 c.c. of water. The liquid is then boiled for a few minutes, after which 10 gm. of glucose are added. After sedimentation at 50° C. the medium can be filtered through paper or cotton and tubed. This medium is used only for stab cultures. Diffusion of the growth through the medium in the case of very motile organisms, such as the typhoid bacillus and the production or absence of gas, are the criteria sought for.

Hiss' Plate Medium.—Hiss utilized the tendency of the typhoid bacillus to form threaded colonies when grown on soft media, as a means of differentiation from the colon bacillus. The medium, as first proposed, contained 15 gm. of agar, 15 gm. of gelatin, 5 gm. each of Liebig's extract and of sodium chloride, 10 gm. of dextrose, and 1,000 c.c. of distilled water. This was cleared by the addition of the whites of two eggs and filtered through absorbent cotton. The reaction was left acid, and of such extent that it would require the addition of 2 c.c. of normal alkali to make it neutral to phenolphthalein. Subsequently Hiss made various modifications of this formula, eliminating the unnecessary constituents. The simplest combination, which was found to give excellent results, was made by adding 15 gm. of agar and 5 gm. of Liebig's extract to 1,000 c.c. of distilled water. No acid or alkali was added. The medium was cleared by the whites of two eggs and filtered through cotton. Plate cultures, made at 37° C., show excellent differentiation between the colonies of typhoid and colon bacilli in twenty-four hours. The former show threaded colonies, the latter do not.

Hesse's Nährstoff-Heyden Agar.—The "Nährstoff-Heyden" is an albumose made from egg albumen. It should first be stirred up in a beaker with a little water, and then added to the liquid. For cultivating the tubercle bacillus the medium consists of: 5 gm. Nährstoff-Heyden, 5 gm. salt, 30 gm. glycerin, 10 gm. agar, and 1,000 c.c. of distilled water; 5 c.c. of normal soda solution are added. The latter represents a 14.3 per cent. of the crystalline salt ($Na_2CO_3 + 10\,H_2O$) and not 28.6 per cent., as stated by Hesse. The Hesse-Niedner agar, which has been recommended for the study of water bacteria, is made by dissolving 7.5 gm. of Nährstoff-Heyden and 12.5 gm. of agar in 1,000 c.c. of distilled water. Gage and Phelps dissolved one per cent. each of agar and of the Nährstoff in 1,000 c.c. of distilled water, and made the solution neutral to phenolphthalein.

Blood Serum.—The preparation of serum from small animals has been described at length under serum agar. When it is desirable to use large quantities of serum it is advisable to collect ox blood at a slaughter-house. The more care taken in collecting the blood under aseptic conditions the less troublesome will be the subsequent sterilization. A convenient receptacle is a half-gallon battery jar covered with paper and previously sterilized. The spurting blood is received directly into the jar, after which the paper cap is replaced and the blood set aside until it firmly clots. It can then be transported to the laboratory and set aside in a cool place for the serum to separate. The serum can then be drawn up by means of an aspirator into a sterile globe receiver, such as is shown as a part of Fig. 5060. It can then be conveniently filled into test tubes or into flasks.

The earliest method of sterilizing blood serum is that of Koch by fractional heating. The tubes were placed in an inclined position in a serum coagulator shown in Fig. 5057. The Roux water bath, shown in Fig. 5063, is particularly useful for this purpose. The serum tubes are immersed in the water at 58° C. The serum tubes are heated for an hour at 58° C. on each of seven successive days. This low temperature is selected in order to accomplish the sterilization and yet keep the serum in a fluid condition. Unfortunately bacteria may be present in the serum which will actually grow at the temperature employed, and in that case this method of sterilization is inapplicable. Some have endeavored to obviate this difficulty by filtering the serum through a Berkefeld

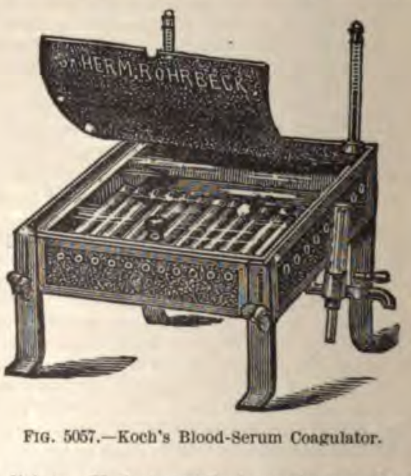

FIG. 5057.—Koch's Blood-Serum Coagulator.

bougie. Martin suggested that one to two per cent. of chloroform be added to the serum, which is then set aside for several months, after which the chloroform can be driven off by heating at 65°. Fraenkel dispensed with the sterilization, relying entirely upon the aseptic collection of the serum. When the serum is collected with the care outlined above, it will be found that very few bacteria are present. Consequently after the tubes have been filled with the serum they may be incubated for several days, and at the end of that time the contaminated ones can be discarded. This procedure is preferable to those just given. The sterile serum is then coagulated in an inclined position by raising the temperature of the sterilizer to 65° C., and keeping it there until the serum has become solid. The medium thus prepared is transparent and solid. When a higher temperature is used the serum coagulates to an opaque white mass.

Inasmuch as the above methods require much time and skill and are in themselves very tedious, they have been largely supplanted by fractional sterilization in steam. For this purpose the tubes are first placed in an inclined position, either in a dry-heat oven, or, better, in the coagulator, and then heated to 85° to 95° C. until firm coagulation results. If this is not looked after the medium will be torn up by gas bubbles during the next step. The coagulated serum tubes are then placed in wire baskets and steamed, as in the case of agar, for half an hour on each of three consecutive days. The medium thus prepared is fully as useful as that which is transparent.

Löffler's Blood Serum.—This consists of one part of a one-per-cent. glucose bouillon and of three parts of blood erum. This mixture is filled into tubes and sterilized in he manner just given. It is used very extensively for he diagnosis of diphtheria.

Glycerin Serum.—Five per cent. or more of glycerin is dded as in the case of glycerin agar. The sterilization the same as that just given. It is used for the culti- ation of the tubercle bacillus.

Serum Water Media.—When serum is diluted with five ten parts of water it can be sterilized by steaming ithout coagulation taking place. Hiss employed such medium in differentiating between the pneumococcus d streptococcus; also in distinguishing between the sentery and allied organisms. He prepares the me- um by adding one part of clear beef serum to two rts of distilled water. The mixture is first heated to 0° for a short time, so as to destroy the glycolytic zyme which is present, after which one per cent. of e sugar desired is added. Dextrose, galactose, man- e, maltose, lactose, saccharose, inulin, and dextrin ve been thus used. The medium is colored by the dition of one per cent. of a five-per-cent. aqueous lit- s solution. The medium is then tubed and steamed ten minutes on three consecutive days.

armorek's Media.—In order to maintain streptococci their maximum virulence Marmorek used several me- , preference being given to them in the following er:

. Human serum 2 parts, bouillon 1 part.
. Pleuritic or ascitic fluid 1 part, bouillon 2 parts.
. Serum of mule or ass 2 parts, bouillon 1 part.
. Horse serum 2 parts, bouillon 1 part.

hese media can be sterilized by fractional heating at temperature, or, better, by filtration through a kefeld bougie.

halmann's serum bouillon for cultivating the gono- us has been mentioned in connection with his agar.

ilk.—This is an excellent medium for diagnostic pur- s. It is advisable to use centrifugated milk if pos- . Otherwise the whole milk is placed in a beaker sk and steamed for about half an hour. When par- y cooled it can be poured into a large separatory el, or into a bulb receiver shown as part of Fig. , and allowed to stand thus overnight. The under- g layer of fat-free milk can then be filled directly tubes. These are then sterilized by steaming half an hour on each of three consecutive days. When time is an object the whole milk may be filled directly into tubes. If desired the milk may be colored with litmus. Instead of milk, whey may be used to good advantage. This can be prepared by coagulating the milk with rennet. The liquid is first separated by means of cheesecloth and finally put through paper. It is then colored with litmus, filled into tubes, and sterilized. Care must be taken not to overheat the milk lest the lactose undergo more or less oxidation. Whey-gelatin and whey-agar are used for special purposes.

Urine.—By discarding the first portion of urine which is passed the remainder can be collected in sterile flasks and will be free from bacteria. Such urine may be used directly for studying the various fermentations which it may undergo. To prepare a urine gelatin the secretion should be diluted so as to have a specific gravity not to exceed 1.010. Ten per cent. of gelatin is then added, and when it has dissolved the reaction is made to correspond to that of the original urine. Heller's urine gelatin is prepared in the same way, but has one per cent. peptone and a half per cent. of salt. After solution the liquid is rendered faintly alkaline, then filtered and tubed.

Piorkowski Urine Gelatin.—Normal urine of 1.020 specific gravity is collected for two days, and is allowed to become slightly alkaline in reaction. Then 1.5 per cent. peptone and 3.3 per cent. gelatin are added, and the mixture is heated for one hour on the water-bath, after which it is filtered and filled into tubes. These are sterilized by heating for fifteen minutes at 100° on the first day, and for ten minutes on the second day. The medium is used to differentiate the typhoid from the colon bacillus. Petri plates are made and developed at 22° C. for twenty-four hours. While the colon colonies are roundish, finely granular, sharp-bordered, and yellowish, the typhoid colonies are small and show a more or less marked threaded border. This method has given good results in connection with the examination of typhoid fæces.

Urine Agar.—This can be prepared by adding to the freshly passed urine two per cent. of finely cut agar. The mixture is then boiled until solution results, when it is filtered through cotton or paper as in the case of ordinary agar. This agar is then filled into tubes and sterilized by steaming.

Another way of preparing a urine agar is to collect the urine, after discarding the first portion which is passed, in a sterile flask, and then to transfer it by means of a pipette, as in the case of blood or serum, to the melted and cooled agar. One part of urine to two parts of agar is ordinarily used. Normal or albuminous urine may be used for this purpose, and with very little care the urine can be collected entirely free from bacteria. Such urine agar has been used to advantage for growing the gonococcus.

Internal Organs.—For special use the several media, such as bouillon, agar, and gelatin, may be made up with the finely divided organs in place of the minced meat. At times the solid organs are sterilized and used as such. The steamed brain, for example, when cut up into slices and sterilized, can be used for cultivating the tubercle bacillus (Ficker); and also the gonococcus (Thalmann).

Egg Media.—Hueppe first suggested the use of fresh eggs as a culture medium. For this purpose the shell is thoroughly cleaned and disinfected with mercuric chloride. A small opening is then punched through the shell, and through this the organism to be tested is introduced into the inside. The opening is then sealed with a bit of sterile paper and collodion. Another procedure is to insert through the opening in the shell a rather wide, drawn-out tube pipette. On applying suction, especially with the aid of an aspirator, the contents of the egg can be drawn up into the bulb, and can then be distributed to tubes (Novy).

The egg may be used as a solid opaque medium according to Wesener. The egg is thoroughly agitated so as to mix the yolk with the albumen. It is then coagulated at 75° to 80° C., after which the shell is removed and the contents are cut up into slices and placed in suitable dishes and sterilized by steam In like manner the coagulated white of the egg may be cut up into slices and tubed. A transparent, coagulated egg albumen may be prepared by converting it into an alkali albuminate, as suggested by Tarchanow and by Karlinski. For this purpose the egg is placed in ten-per-cent. potash for fourteen days, after which the shell is removed and the solidified egg is cut up into slices, tubed, and sterilized.

Potatoes.—These may be prepared in several ways. The old method, introduced by Koch, is still used where mass cultures are desired. The potatoes are scrubbed clean under the tap, and any bad spots carefully removed by means of a knife. They are then placed in boiling water or steamed for three-quarters of an hour. By means of a knife, which has been sterilized in a flame, they are then cut into halves and placed in a large moist chamber or suitable pan provided with a lid. The bottom of this vessel should first be covered with a piece of filter paper which has been moistened with water or with mercuric chloride. The cut and sterile surface of the potatoes can then be inoculated with the organisms to be cultivated, either by spreading the material over the potato with a sterile knife or by making parallel streaks. Inasmuch as there are several sources of contamination in this method, it has been largely displaced by the modified procedures.

In Esmarch's modification the potato is pared and cut into slices about a third of an inch thick, after which they are placed into small glass dishes about 7 cm. in diameter and 1 cm. high, known as Esmarch dishes. These are then sterilized by steaming in the usual way.

The best way of using potatoes for culture purposes is that introduced independently by Bolton and Globig. The cleaned potato is placed in boiling water for about half an hour. By means of a cork borer or a test tube, the end of which has been cut off, cylinders of potato may be punched out. The skin is removed from the ends of the cylinders, after which these are halved by a diagonal cut. The wedge-shaped semicylinders are now placed in sterile test tubes and sterilized by steam.

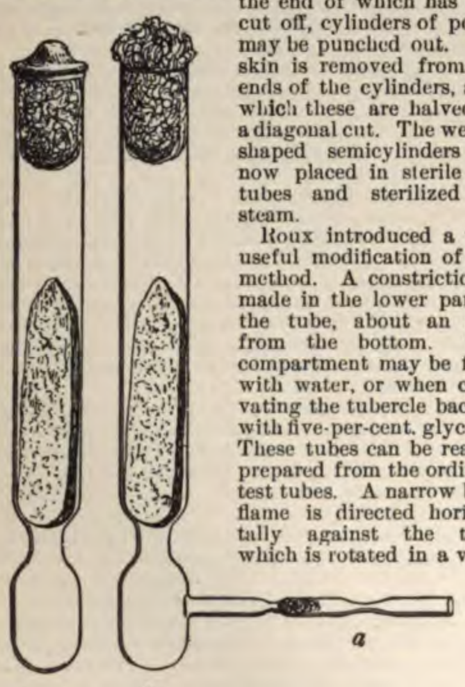

FIG. 5058.—Roux Tube for Potato Culture.

Roux introduced a very useful modification of this method. A constriction is made in the lower part of the tube, about an inch from the bottom. This compartment may be filled with water, or when cultivating the tubercle bacillus with five-per-cent. glycerin. These tubes can be readily prepared from the ordinary test tubes. A narrow blast flame is directed horizontally against the tube, which is rotated in a vertical position. The Roux tube is shown in Fig. 5058. A good substitute for this tube may be made by placing on the bottom of the test tube a layer of absorbent cotton, which may be soaked with the glycerin solution.

Mashed potatoes spread over the bottom of a flask have been used, but they offer no special advantage over the methods given. The preparation of potato gelatin with or without potassium iodide has already been described

Bread Medium.—Ordinary bread is toasted to a crisp, then powdered, in which condition it may be kept in stock. For use the powder is placed on the bottom of small flasks and thoroughly moistened with water, then sterilized by steaming. This medium is particularly useful for cultivating moulds.

Plant Infusions.—These are useful for growing certain bacteria and also amœbæ. Infusions of hay, straw, fruits, grains, etc., take the place of meat extract. By the addition of agar or gelatin solid media may be prepared. Beer wort, either as such or as a gelatin, is valuable for the cultivation of yeasts.

Proteid-free Media.—With the exception of urine all the media described thus far contain some proteid matter. The latter, however, is not essential, for it is possible to grow bacteria on media which contain sulphur, nitrogen, and phosphorus in inorganic combination. Such a solution was used, for instance, at a very early date by Pasteur It consisted of 1 part of ammonium tartrate, 10 parts of candy sugar, the ash of 1 part of yeast, and 100 parts of water. The botanist Cohn employed a similar solution, consisting of 0.1 gm. each of potassium phosphate and magnesium sulphate, 0.01 gm. of tribasic calcium phosphate, 0.2 gm. of ammonium tartrate, and 20 c.c. of distilled water. Naegeli's solution was made by adding 1 gm dibasic phosphate, 0.2 gm. magnesium sulphate, 0.1 gm. calcium chloride, and 10 gm. of ammonium tartrate to 1,000 c.c. of distilled water.

After the lapse of many years these non-albuminous fluids were again brought into use in a modified form by Uschinsky His solution consisted of: Water, 1,000 parts; glycerin, 30–40 parts; sodium chloride, 5–7 parts; calcium chloride, 0.1 part; magnesium sulphate, 0.2–0.4 part; dipotassium phosphate, 2–2.5 parts; ammonium lactate, 6–7 parts; sodium asparaginate, 3–4 parts.

Fraenkel's modification of this solution contains 5 gm. of sodium chloride, 2 gm. of potassium diphosphate, 6 gm. of ammonium lactate, and 4 gm. of sodium asparaginate. These substances are dissolved in 1,000 c.c. of water and the solution is then rendered slightly alkaline.

Similar solutions have been used by Maassen and by others. Thus Proskauer and Beck cultivated the tubercle bacillus on the following solution: Commercial ammonium carbonate, 0.35 per cent.; monopotassium phosphate, 0.15 per cent.; magnesium phosphate, 0.25 per cent.; glycerin, 1.5 per cent.

For cultivating the nitrous and nitric acid organisms Winogradsky employed wholly inorganic solutions. The nitric-acid producers were grown in a solution consisting of 1,000 c.c. of water, 1 gm. potassium phosphate, 0.5 gm. magnesium sulphate, 0.01 gm. calcium chloride, 2 gm. sodium chloride. This is filled into flasks in portions of 20 c.c. each, together with a little freshly washed magnesium carbonate. To these flasks, after sterilization by steam, 2 c.c. of a two-per-cent. solution of ammonium sulphate is added, after which they are incubated to eliminate contaminations.

For the nitrous-acid organisms the solution consists of 1 gm. ammonium sulphate, 1 gm. potassium sulphate, and 1,000 c.c. of water. It is filled into flasks, magnesium carbonate added, after which they are sterilized by steam.

As a substitute for gelatin Winogradsky employed silicic-acid jelly, which was added to solutions of essentially the same composition as those just given.

Standardization of Media.—The procedure as introduced by Koch, and still followed in many laboratories, is to add a saturated solution of sodium carbonate, in portions of a cubic centimetre or more, to the nutrient medium, to be neutralized until a drop of the mixture, transferred by means of a glass rod, turns red litmus paper promptly blue. In some laboratories a strong solution of sodium hydrate is used in the same way. Obviously this method lacks quantitative precision, and the duplication of the same reaction in several batches of material is out of question. Moreover, it is an established fact that the reaction of a medium has a very important influence upon the development of bacteria. For these reasons the bacteriological committee of the American Public Health Association, adopting Fuller's work, recommended the following method for the titration of nutrient media. The reagents necessary are:

1. Five-tenths-per-cent. solution of phenolphthalein in fifty-per-cent. alcohol.
2. Normal sodium hydrate (N. NaOH). A litre of this solution contains 40 gm. of NaOH.
3. Twentieth normal sodium hydrate ($\frac{n}{20}$ NaOH). A litre of this solution contains 2 gm. of NaOH.
4. Normal hydrochloric acid (N. HCl). A litre of this contains 36.5 gm. HCl.
5. Twentieth normal hydrochloric acid ($\frac{n}{20}$). A litre of this contains 1.825 gm. of HCl.

The preparation of these solutions requires some familiarity with the methods of quantitative analysis. The solutions can be built up by starting from a twentieth normal solution of oxalic acid, or, better, succinic acid.

The titration is carried out as follows: To 5 c.c. of the filtered medium in a six-inch porcelain evaporating dish add 45 c.c. of distilled water and 1 c.c. of the phenolphthalein solution; boil for three minutes to expel carbonic acid, then run in the twentieth normal alkali, drop by drop, with constant stirring, until a bright pink color results. The number of cubic centimetres of the twentieth alkali required to neutralize 5 c.c. of the medium gives directly the number of cubic centimetres of normal alkali (*i.e.*, percentage) required by 100 c.c. of the medium. Thus if 5 c.c. of the medium requires 2.8 c.c. of $\frac{n}{20}$ alkali, then 100 c.c. would need 56 c.c. $\frac{n}{20}$, or 2.8 c.c. of N NaOH.

The quantity of the medium remaining is now measured and the amount of alkali needed for neutralization s calculated and added. After the addition of the alkali he liquid is boiled and a portion is then titrated as beore. It should be neutral, and if it is not, as often is he case on account of unknown changes, the requisite mount of alkali to make it so is added to the bulk.

The medium which is neutral with reference to phenolhthalein is very alkaline with respect to litmus. Thus bouillon which is neutral to litmus will require about 5 c.c. of normal alkali per litre to make it neutral to henolphthalein. In general the addition of 10 c.c. of ormal alkali to a medium which is neutral to litmus nparts the most favorable degree of alkalinity. Hence e optimum reaction with reference to phenolphthalein obtained by adding 15 c.c. of normal acid to the litre f neutralized medium. It is customary to use the sign - to indicate an acid reaction, and that of – for one that alkaline. Thus + 15 means that the reaction is acid ith respect to phenolphthalein, and that one litre of e medium would require 15 c.c. of normal alkali for utralization.

The titration with litmus as an indicator is best carried t in the following way: Portions of 5 c.c. of the meum are measured out into each of four or five large st tubes. In the case of bouillon the amount of $\frac{n}{20}$ alkali eded to neutralize this amount may vary from 0.3 0.6 c.c. Hence to tube 1 add 0.3 c.c.; to tube 2 add 4 c.c.; to tube 3 add 0.5 c.c., etc. The contents of ch tube are then boiled for a minute, after which a slip red and of blue litmus paper is dropped into the hot uid and allowed to remain there for about a minute. e papers are then drawn out, side by side, on the walls the tube when the colors can be compared. In this y the amount of alkali necessary to neutralize 5 c.c. th respect to litmus can be determined. Bouillon, as ll as agar, usually requires about 5 c.c. per litre for tralization, while gelatin needs about 30–35 c.c. ving determined the amount needed for neutralization, s amount, together with an excess of 10 c.c. per litre, impart a suitable alkaline reaction, is then added to medium.

or ordinary purposes it is hardly necessary to resort to these rather complicated methods. It is sufficient to add directly to bouillon and to agar 15 c.c. of normal alkali per litre. Gelatin will require about 40 c.c. In general sodium carbonate is preferable to the hydrate.

Preparation and Filling of Tubes.—The cheaper grades of test tubes should be avoided. They are very thin and therefore break easily, and, moreover, on heating they will often frost because of the separation of silicic acid. The best test tubes are the "blue-lined" or "resistant glass" quality, or those of genuine Bohemian glass. The size used varies with the purpose and the individual taste; 12 × 125, 15 × 150, and 20 × 150 mm. are convenient.

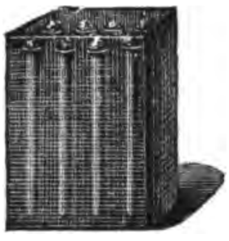

FIG. 5059.—Wire Basket for Sterilizing Tubes.

The new tubes of the better glass can be used after being swabbed out with warm water.

The cheaper grades are very alkaline, and for that reason should be first soaked in very dilute warm hydrochloric acid; after which they should be rinsed or swabbed thoroughly in clean warm water. The cleaned tubes are allowed to drain, and when dry are plugged. Used tubes should be sterilized by steaming for a half-hour, after which they may be filled with water and again heated, so as to bring the more or less dried contents into solution.

The simplest way of plugging is to place over the mouth of the tube a piece of cotton, about two inches square, which is then pushed within by means of a narrow glass rod or a pair of smooth forceps. Such plugs answer all ordinary purposes. They are, however, rather loose, and permit evaporation of the media, and cannot be used where the tubes are to be sealed with wax. A firm solid plug is made by taking a piece of cotton, about three inches square. This is folded into thirds and then rolled up from the end into as firm a cylinder as possible. By a twisting motion the plug is inserted into the tube, and only enough cotton is left on the outside to permit grasping of the plug. The plugged tubes are then placed in a wire basket, such as is shown in Fig. 5059. These baskets are made of heavy galvanized netting. The usual size is 24 cm. high and 18 cm. square. Smaller baskets, 10 × 12 and 18 cm. high, are very useful. Circular baskets, of a size to fit the sterilizer, are also used.

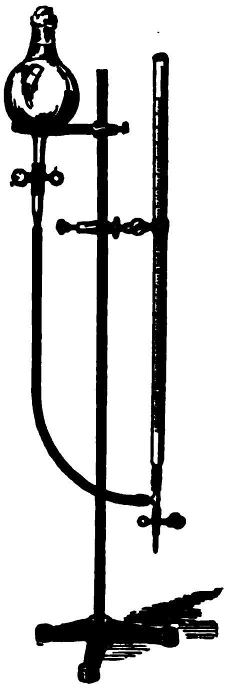

FIG. 5060.—Globe Receiver for Filling Media into Tubes, with Burette Attachment. (Novy.)

Flasks, bulbs, etc., should be prepared for sterilization in the same way.

After the tubes have been sterilized by heating in the dry-heat oven they are ready to be filled with the nutrient media. This can be done by the aid of a small funnel. Where large quantities of media are to be tubed much time can be saved by using a large funnel or globe receiver, such as is shown in Fig. 5060. The lower end of the bulb is connected with a drawn-out glass tube and is provided with a pinch cock. In this way the media can be rapidly filled into the tubes. Ordinarily the tubes are filled to the depth of one and one-half or two inches. In special cases in which definite quantities are desired, the simple apparatus, shown in

Fig. 5060, can be used. The containers, with the media to be filled, can first be sterilized by steaming, after which the media can be measured out into sterile tubes, which will not require further treatment. A less desirable apparatus is that of Treskow, shown in Fig. 5061.

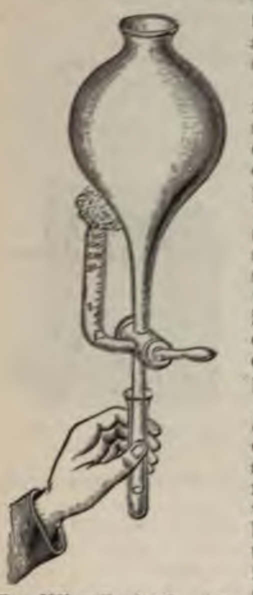

FIG. 5061.—Treskow's Apparatus for Measuring Media into Tubes.

STERILIZATION.—By sterilization is meant the total destruction or removal of all organisms in or about a given object. This can be accomplished in a variety of ways.

1. *By Direct Flaming.*—This method is applicable for the sterilization of glass rods, slides, cover-glasses, platinum wires, searing irons, and rough instruments. Valuable surgical instruments would of course be damaged by this procedure.

2. *By Means of the Dry-Heat Sterilizer.* — The form most often used is that of Koch, shown in Fig. 5062. This is made of sheet iron, is double walled, and the outer wall may be lined to advantage with thick asbestos board. The form as shown is designed to sterilize not only tubes and flasks but also glass tubing, pipettes, and the like. The oven is used for sterilizing only glass and metal ware. It must not be used for sterilizing media. A temperature of 150° C. should be maintained for one hour. Usually it will be sufficient to allow the temperature to rise, and as soon as it has reached 200° the gas is turned off. The cotton should show a slight tinge of yellow after this heating. If the plug browns considerably and powders it is due more to the fact that the cotton has been chemically treated than to the heat.

3. *Fractional Sterilization at* 56°–58° C.—This method was introduced by Tyndall, and has been used for the sterilization of liquid serum, milk, and other fluids which are liable to be altered more or less by heat. It is based upon the fact that the actively vegetating forms of bacteria are readily destroyed as a rule by exposure for some minutes to this temperature. The resting forms or spores are not in the least affected by such exposure. It is necessary to wait until the spores have germinated into the vegetating forms, which can then be destroyed by a second like heating. As ordinarily practised, the method is as follows: The tubes are placed in an apparatus, such as that shown in Fig. 5063, and are heated for one hour at the given temperature on each of seven or eight consecutive days.

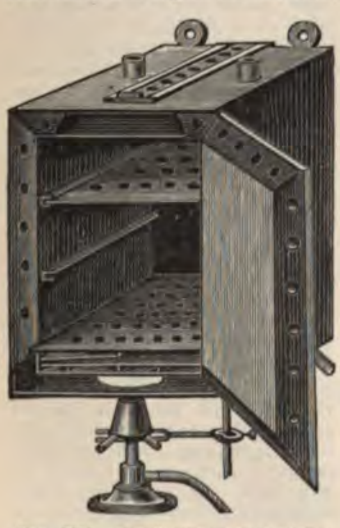

FIG. 5062.—Koch's Dry-Heat Sterilizer.

This method sometimes gives good results, at other times it fails. The reason for this lies in the presence or absence of the so-called thermophilic bacteria. These organisms actually grow best at the temperature employed, and hence, if they chance to be present, the method is inapplicable. A temperature of 70° C. may be used in like manner, but this causes coagulation of the serum.

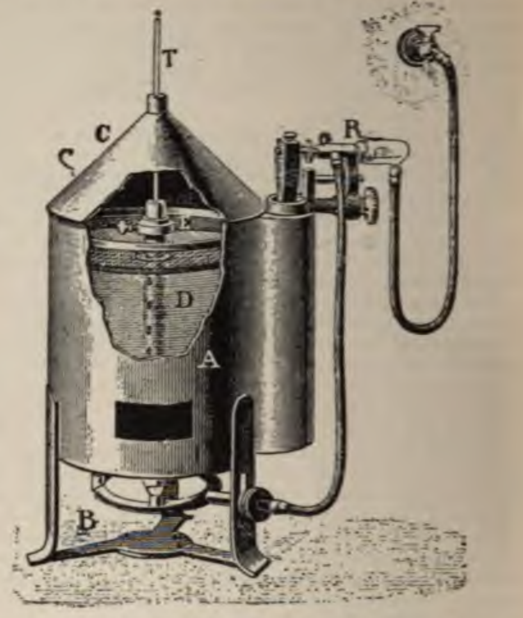

FIG. 5063.—Roux Water-Bath for Sterilizing Serum with Metallic Regulator.

By Pasteurization is meant the partial destruction of the organisms which are present in a milk. This is accomplished by exposing the milk for half an hour, or more, to a temperature of about 68° C. (155° F.). While this temperature does not destroy the spores which may be present, it does kill the lactic-acid and other bacteria, which do not produce spores. As a result, milk treated in this way will keep for several days without coagulating. If a higher temperature is used, the taste of the milk is likely to be impaired.

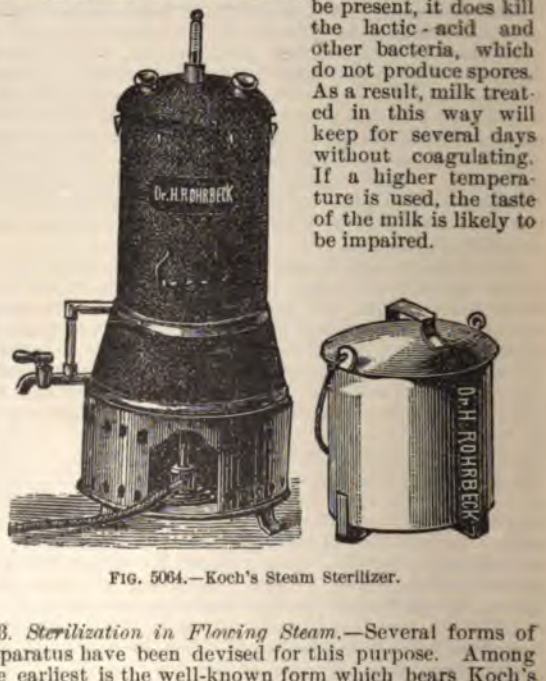

FIG. 5064.—Koch's Steam Sterilizer.

3. *Sterilization in Flowing Steam.*—Several forms of apparatus have been devised for this purpose. Among the earliest is the well-known form which bears Koch's name. This apparatus is used almost entirely in Ger-

many, and to a considerable extent in this country. It is shown in Figs. 5064 and 5065.

It consists of a cylinder of galvanized iron, or better of copper, which can be given such dimensions as may be desired. Ordinarily it is about half a metre high and about 25 cm. in diameter. It is surrounded by a thick covering of felt *M*, to prevent loss of heat by radiation. In the interior of the cylinder at *R*, is placed a grate which serves as a support for the pail and other vessels to be disinfected. The water in the lower compartment is heated by one or more large gas burners. Above it is closed with a cover *D*, which is also covered with felt. A central opening permits the escape of steam, and can be used for the insertion of a thermometer. The pail shown to the right of the sterilizer has a grating for a bottom, to allow free access of the steam, and in it are placed the articles to be sterilized.

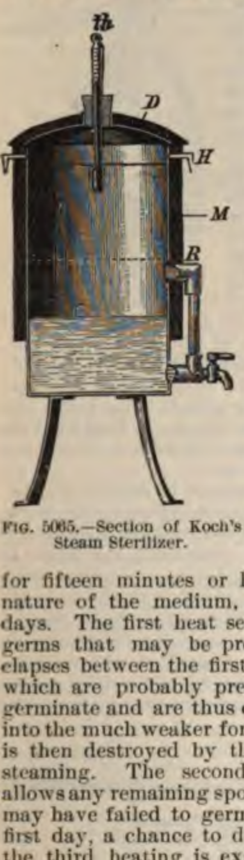

FIG. 5065.—Section of Koch's Steam Sterilizer.

The nutrient media are as a rule sterilized by steam. A single heating for one hour in steam at 100° C. is usually sufficient to render the media sterile. Prolonged heating, however, tends to alter the media, and for that reason fractional or discontinuous sterilization is resorted to. The latter has the additional advantage that it renders the medium more surely sterile. There are spores which can withstand steaming for one, and even five or six hours, and if such forms chance to be present, it is evident that the material cannot be sterilized by the single heating for one hour. In the other procedure the media are steamed for fifteen minutes or half an hour, according to the nature of the medium, on each of three consecutive days. The first heat serves to destroy the vegetating germs that may be present. In the interval which elapses between the first and second heating, the spores which are probably present will germinate and are thus converted into the much weaker form, which is then destroyed by the second steaming. The second interval allows any remaining spore, which may have failed to germinate the first day, a chance to do so, and the third heating is expected to dispose of these last organisms. As a rule all media should be incubated for one or two days to make sure that they are perfectly sterile. If any growth develops in the tubes or flasks these should be discarded, and only those which are free should be preserved for use.

Failure to secure sterilization by this procedure is due to one of the following conditions: The temperature which prevails during the twenty-four-hour period which elapses between the consecutive heats may be so high that the spores which are present not only germinate, but the vegetating forms in turn give rise to spores, so that a larger number of resistant forms are present on the second or on the third day than were present in the beginning. Again, it may happen that the temperature is too low, in which case the spores cannot germinate, and hence will be found to resist sterilization. Another source of error, though much less common, was pointed out by Smith. If the spores of anaërobic bacteria are present in a bouillon, they cannot from their very nature germinate under the ordinary conditions, that is, in the presence of the air, and may therefore escape destruction.

In this country, and even in Germany, the Arnold steam sterilizer has met with a very favorable reception. The apparatus is shown in Fig. 5066. It consists of (*a*) a flat, shallow boiler, holding but a small amount of water, and therefore requiring but a minimum amount of heat to produce steam; (*b*) a reservoir placed upon the boiler, which it constantly feeds and insures the constant formation of steam; (*d*) a covered steam chest or receiving vessel, placed above the reservoir and connected with the boiler by a cylindrical tube of large diameter (*c*); and (*e*) a hood, covering the receiver and enclosing an air space, which is constantly supplied with escape steam. The hood and the steam jacket which it encloses prevent variations in temperature in the receiving vessel so long as the heat applied to the boiler remains unchanged.

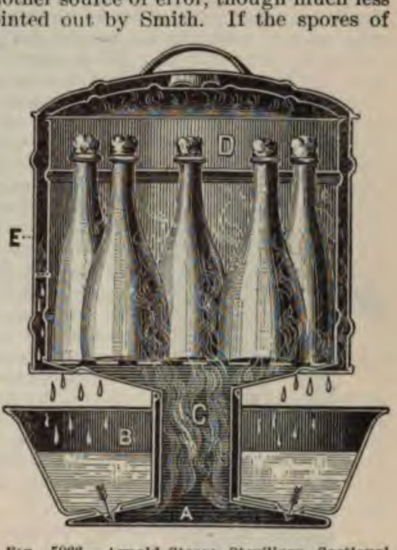

FIG. 5066.—Arnold Steam Sterilizer, Sectional View.

A cheap and thoroughly efficient steam sterilizer adapted for individual work is shown in Fig. 5067. This consists of an ordinary Hoffmann iron water-bath 10–20 cm. in diameter. On this is placed a copper pail (20 × 20 cm.), which is provided with a perforated bottom. Two perforated rings on the inside allow the passage of steam, and prevent the cotton of the tubes from coming into contact with the side of the steamer. The tubes filled with media are placed in the pail, and this is then set on the water-bath, the water of which has been previously raised to active ebullition. In a few minutes steam will issue from the tube in the top of the cover. It is always advisable to take the temperature of the vapor as it issues from a sterilizer and to count the time of exposure from the moment that the vapor actually shows the temperature of steam, that is 100°.

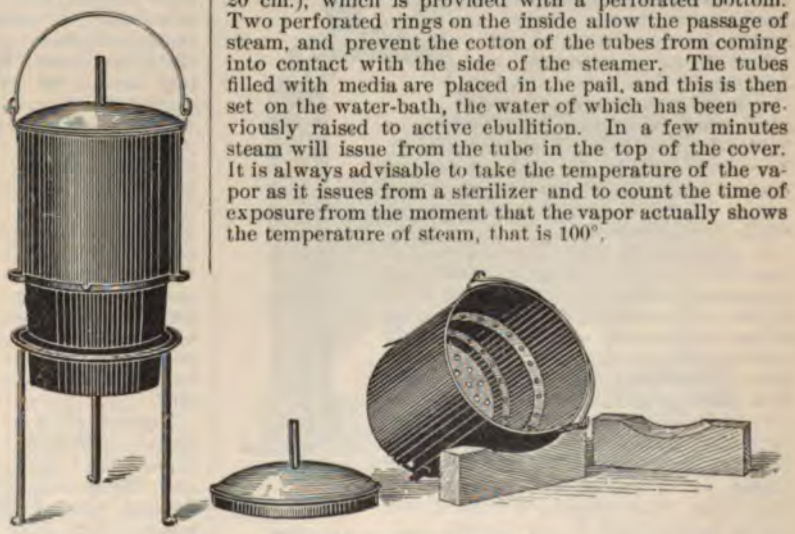

FIG. 5067.—Novy Steam Sterilizer.

4. *Sterilization by Steam Under Pressure.*—This procedure is used almost entirely by the French workers. Its usefulness is such as to merit a wide introduction into this country. The apparatus, which is designated as an

autoclave, is shown in Fig. 5068. It consists of a strong boiler, in the bottom of which a small quantity of water is placed. The articles to be steamed are placed in a wire basket, which is set on the bottom of the boiler. The lid is closed with a rubber gasket and securely held in place by thumb screws. Inasmuch as the amount of aqueous vapor in a given space as well as the temperature, in the case of confined steam, is greater than with flowing steam, it follows that the autoclave is considerably more efficient. Thus steam at 130° C., under pressure, will destroy instantaneously spores which would resist flowing steam at 100° for five or six hours.

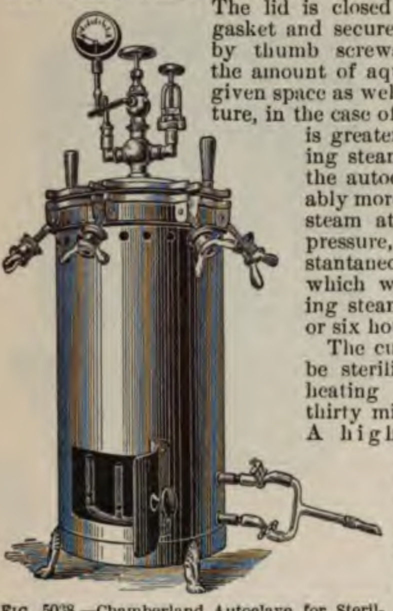

FIG. 5068.—Chamberland Autoclave for Sterilizing by Steam Under Pressure. (Novy.)

The culture media can be sterilized by a single heating for fifteen to thirty minutes at 110° C. A higher temperature should be avoided, as it tends to alter the reaction of the media. Glass apparatus, filters, rubber, etc., can be sterilized by heating at 120° for half an hour. Infected animals can be subjected to 120° for the same length of time, or to 130° or more for a less period.

It must be remembered that the autoclave requires more care than an ordinary sterilizer owing to the danger of explosion. The following points should be observed in its use: Enough water should be present; after the burners are lighted, the steam valve should be left open until all the air has been expelled, when the steam has flowed rapidly for one or two minutes the valve is closed; as soon as the desired temperature is indicated on the gauge, the burners are turned down, so that this temperature is maintained for the required time; the burners are then turned off, but the steam valve is not opened until the temperature has fallen below 100°, after which the lid can be removed. The safety valve should be tested to open at about 125° C. It is a good rule not to leave the autoclave out of sight while the temperature is rising.

5. *Sterilization by Filtration.*—It is possible to remove completely all the organisms which may be present in a liquid by filtration. Filter paper, of course, on account of the small size of the bacteria cannot be used for this purpose. There are only two reliable filters for bacteriological work. That known as the Pasteur-Chamberland filter is the best, and is made of unglazed porcelain. The form, as used for filtering water for domestic use, is shown in Fig. 5069. The original French filters are to be preferred to the German imitations. They are made in two grades; that marked *F* is more porous than that marked *B*.

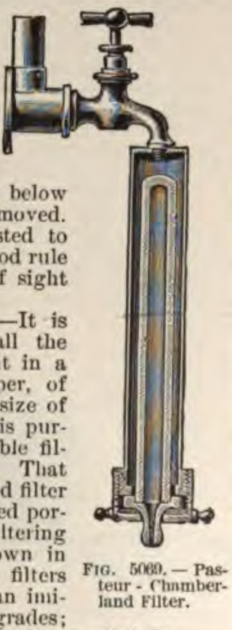

FIG. 5069. — Pasteur - Chamberland Filter.

The Kitasato filter, a narrow form of the above, is also made of unglazed porcelain, and is intended for the filtration of very small amounts of liquid. This can, however, be done also with the former. It is shown in Fig. 5070.

The Berkefeld filter (Fig. 5074) consists of closely packed infusorial earth. It can be obtained in several sizes, having the general shape of the Chamberland Pasteur bougie. It is considerably more porous than the porcelain filter, and is therefore adapted for rapid filtration, but it should be borne in mind that it is more likely to allow the passage of bacteria.

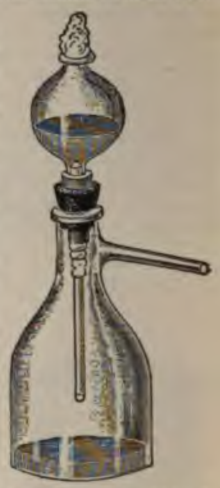

FIG. 5070.—Kitasato's Filter.

A useful form of apparatus for holding the Pasteur-Chamberland bougie, that of Martin, is shown in Fig. 5071. It consists of a metal cylinder with a funnel-shaped top, which permits the filtration of the culture through filter paper previous to its passage through the bougie, and thus obviates or lessens the clogging of the latter. A rubber ring serves to make a tight joint when the bougie is held in place by the lower screw cap. The lower end of the bougie is connected with a piece of vacuum rubber tubing to a globe receiver. The entire apparatus is sterilized by heating in an autoclave. The filtration may be carried on by gravity or an aspirator may be connected with the upper tube of the globe receiver. When the filtrate is to be transferred, the drawn-out side tube is scratched near the end with a file, and then broken off, after which the tube is flamed and the liquid is drawn off into sterile tubes or flasks. This globe receiver can be used until the drawn-out tube is too short, when a new tube is fused on.

A better form of a globe receiver is shown in Fig. 5074. This is provided with three side tubes, which are plugged with cotton, after which the receiver is sterilized in a dry-heat oven. When it is to be used, the cotton is removed from the tube *D*, which is then connected with the sterile bougie by means of a piece of sterile vacuum tubing. The horizontal tube *F* is similarly connected with the sterile drawn-out glass tube *G*. The tube *E*, with its cotton plug in place, is connected with a Chapman pump. The filtrate may be withdrawn by means of a sterile bulb pipette, or in the same way as from the receiver of Martin. The advantage lies in the short rubber tubing, compactness, and the convenience in attaching the drawn-out tube. This vacuum receiver can be obtained in several sizes, such as one-quarter, one-half, one, and one and one-half litre capacity.

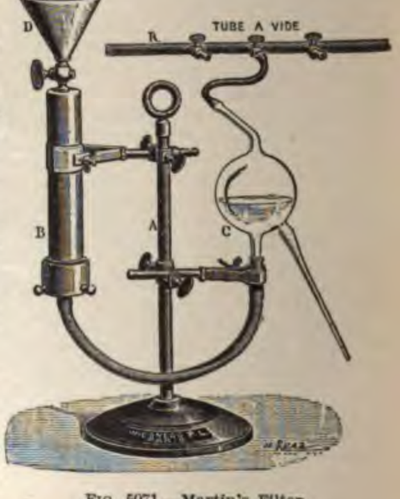

FIG. 5071.—Martin's Filter.

Instead of a metal cylinder to hold the bougie, Novy has devised one of glass. This is shown in Fig. 5072. The necessary tight joint between the bougie and the glass cylinder is made with a rubber ring, and the bougie is brought up tight into place by means of small vises, which act on the flange and on an iron washer. The arrangement is shown in Fig. 5073. If desired the liquid can be filtered under pressure, in which case the rubber stopper at *H* is connected with a tank of compressed air. The cylinders are made to withstand a pressure of over one hundred pounds.

The Berkefeld filter may be attached to the above glass cylinder by means of a rubber and iron washer and the clamps mentioned (Fig. 5074). A more convenient arrangement is to use a cylinder of brass of suitable length and width, threaded at each end The lower end is provided with a screw cap, through which the metal end of the Berkefeld bougie is passed The upper end is also closed with a screw cap, provided with a three-eighths of an inch nipple, hich serves to connect the cylinder with the compressed ir The tip of the Berkefeld is connected with a globe ceiver. The filtration can then be carried out by grav y, by aspiration, or by pressure.

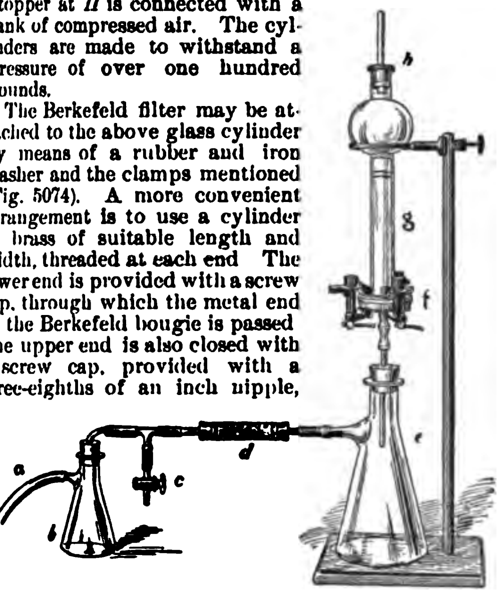

Fig. 5072.—Novy's Filtering Apparatus.

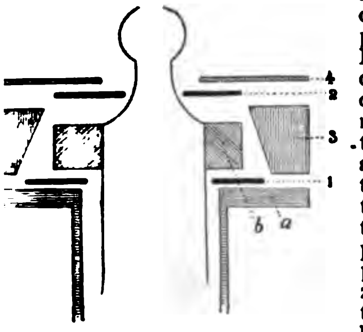
The filtration of liquids constitutes an exceedingly imortant part of bacteriological technique. By its means e soluble products of bacteria may be separated from e solid cells. In this way the toxins of many pathoenic bacteria are prepared. Again it is by the filtration ocess that it has been possible to demonstrate the existce of the so-called ultra-microscopic organisms. While e common bacteria will not pass through a filter, there e a number of diseases in which the cause is so minute at it will go through the Berkefeld, and at times, even rough the Pasteur-Chamberland bougie. Yellow fer, sheep pox, foot-and-mouth disease, contagious pleu-pneumonia of cattle, chicken pest, rinderpest, horse kness, molluscum contagiosum of birds, and the osaic disease of tobacco" are of this class. So also is at of rabies. The fact that a given filtrate infects is proof that the cause is always in this extremely mite form. It may be that the real organism is relatively large, as in the case of the rat trypanosome, and yet Berkefeld filtered cultures of this will often infect animals. This is due to the existence of a minute stage in the development of the organism. It is therefore to be expected that the pathogenic protozoa, though they themselves may be large, may give rise to filterable sporozoites.



5073.—Connections for the Novy Apatus. 1, 2, 3, Rubber rings; 4, iron sher.

6. *Sterilization by nicals.*—This principle is applicable only to a limited nt to nutrient media. The addition of such subces as carbolic acid or mercuric chloride will serve to destroy the organisms which may be present, but since these compounds cannot be removed from the medium, it follows that it cannot be used for culture purposes. A few substances have, however, been used with this object in view. Thus if chloroform is added to milk or blood serum, and is allowed to act long enough, it will bring about sterilization. The remaining chloroform can finally be driven off by means of gentle heat and by aëration. Ether has been used in the same way, and indeed this is a useful procedure for sterilizing such weak cultures as those of cholera.

Glycerin, as is well known, is added to vaccine with the object of destroying the common pus-producing organisms which are so often present. It certainly will in time destroy all of these accidental bacteria, but unfortunately prolonged exposure of the vaccine virus to the glycerin damages it as well.

Chemical disinfection of drinking-waters has also been proposed, especially in connection with military operations. For this purpose various substances, such as bromine and the organic peroxides, have been suggested

In the laboratory this method is resorted to more or less to sterilize old used cultures, test tubes, and even animals. Five-per-cent. carbolic acid or 0.1-per-cent. mercuric chloride are employed.

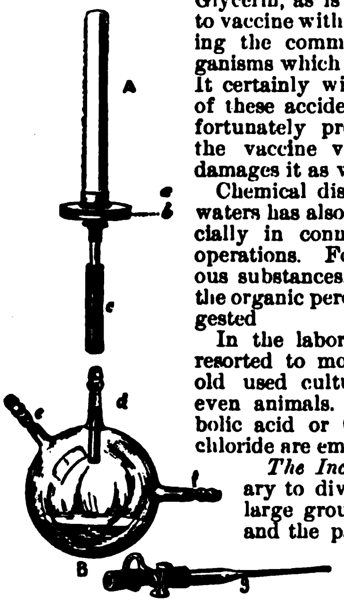


Fig. 5074. — Berkefeld Filter showing Manner of Attachment. Globe receiver. (Novy.)

The Incubator.—It is customary to divide bacteria into two large groups — the saprophytic and the parasitic—according as to whether they grow in nature on dead matter or in the living body. Among the latter are classed the disease-producing bacteria. In general the optimum temperature for the growth of the saprophytic organisms is about 25° C., whereas the pathogenic bacteria thrive best at the temperature of the body. In order to supply this requirement it is necessary to use an incubator or thermostat, the temperature of which can be maintained without variation at any desired level. Various forms of apparatus have been devised for this purpose; that of Koch is shown in Fig. 5075. It consists of a double-walled box of copper, the sides and top

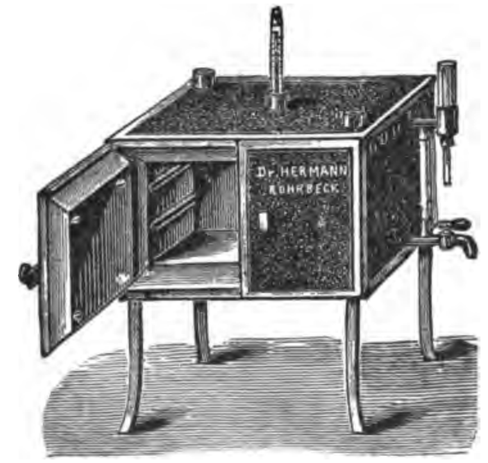

Fig. 5075.—Koch's Incubator.

being covered with felt. The space between the walls is filled with water. In the top is an opening communicating with the interior air space, and in it a thermometer is placed to indicate the temperature. The openings in the corners communicate with the water space. One of these is intended to hold a thermo-regulator, while the other serves for the addition of water. Inner and outer doors are provided, and in the better models provision is made for ventilation and for keeping the air moist.

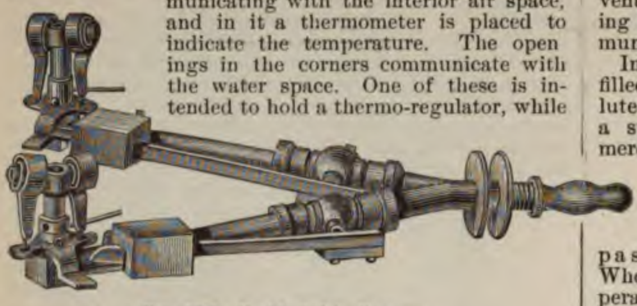

FIG. 5076.—Koch's Safety Burners.

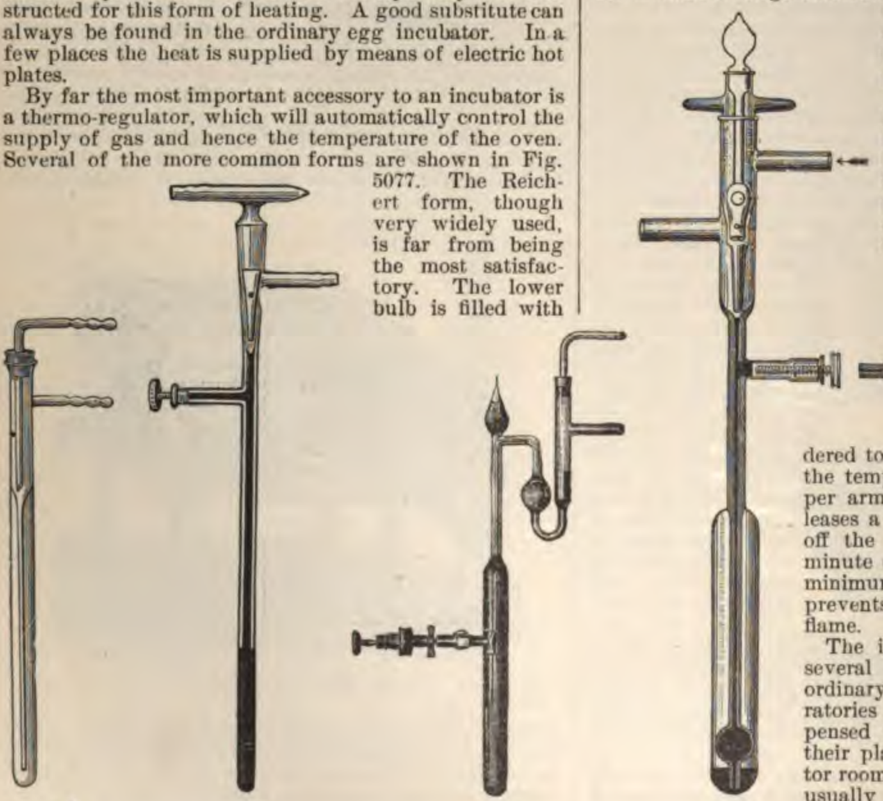
The apparatus may be heated with an Argand burner The ordinary Bunsen burner is not used because of the danger of "shooting back." The Koch safety burner is to be preferred, for it automatically shuts off the supply in case the gas should by any chance happen to be turned off. It consists of two iron spirals which, as they are heated, expand, and in so doing communicate this motion to an arm which then swings under and supports the weighted lever of the valve. If by any accident the flame should become extinguished, the spirals cool and contract; this causes the supporting arm to swing out from under the lever, which then falls and thus shuts off the gas (see Fig. 5076).

In case gas is not available the incubator is heated with an oil lamp. The Sartorius model is especially well constructed for this form of heating. A good substitute can always be found in the ordinary egg incubator. In a few places the heat is supplied by means of electric hot plates.

By far the most important accessory to an incubator is a thermo-regulator, which will automatically control the supply of gas and hence the temperature of the oven. Several of the more common forms are shown in Fig. 5077. The Reichert form, though very widely used, is far from being the most satisfactory. The lower bulb is filled with mercury, which as the temperature rises shuts off the opening through which the gas enters. In order to prevent the flame from being extinguished a minute opening is made in the gas delivery tube whereby a minimum flame can be maintained.



A. B. C. D.

FIG. 5077.—Thermo-Regulators. *A*, Bunsen's; *B*, Reichert's; *C*, Dunham's; *D*, Novy's.

In the Bunsen form the lower compartment is nearly filled with a mixture of equal parts of ether and absolute alcohol, after which a sufficient quantity of mercury is added to act as a valve. The upper part is closed with a stopper, through which passes the gas tube. When the proper temperature is reached, this tube is pushed down till the gas flame drops. The minimum opening prevents total extinguishment. By careful manipulation the regulator can be set at any temperature which may be desired.

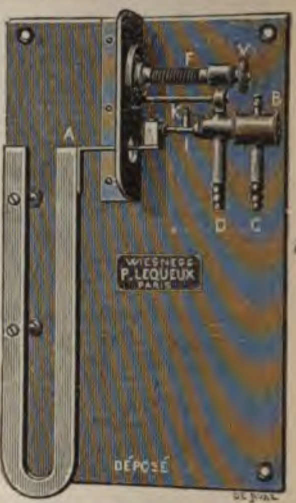


FIG. 5078.—Roux Metallic Thermo-Regulator.

In both the Novy and Dunham forms the lower bulb is filled with absolute alcohol. As this expands it acts against a column of mercury, which in turn shuts off the supply of gas. The lateral screw permits the adjustment of the regulator to the desired temperature. In the former the minimum supply can be regulated to a nicety. This enables it to be used for a water-bath, or for a small or large incubator. It can be obtained with the alcohol cylinder of different sizes, according to the use for which the apparatus is intended.

The metallic regulator of Roux is intended for controlling the temperature of large water-baths and of incubator rooms, for which purpose no better device can be found. It is made in the two forms, the straight and the **U** shape, shown in Fig. 5078. It consists of two metal bands having different coefficients of expansion. These are soldered together the full length. As the temperature rises, the free upper arm moves from and thus releases a spring valve, which shuts off the main supply of gas. A minute opening serves to supply a minimum amount of gas, and thus prevents extinguishment of the flame.

The incubator described in its several modifications answers all ordinary purposes. In large laboratories they can, however, be dispensed with almost entirely, and their place is taken by the incubator room. By this is meant a room, usually about eight feet cube, which is maintained at a constant temperature. This arrangement was first employed at the Pasteur Institute, where the heat is conveyed to the room by means of large pipes along the wall, filled with water, or better with glycerin. The circulating liquid is heated by a small gas stove placed on the outside of the room.

A more simple and thoroughly efficient procedure is to place a small gas stove in the centre of the room. This stove, which can be obtained of the French dealers, is so constructed that the gases of combustion are carried out of the room into a flue.

Another procedure of limited application is to heat the room with steam coils. The regulation of the heat in this case is accomplished by means of an automatic steam valve operated by compressed air.

The construction of the room requires no special care. The walls, whether of brick or of plaster, should be given several coats of white zinc. Shelves, water, gas and electric light, and a window should be provided.

The regulation of the temperature in the rooms heated by gas is done by means of the Roux **U**-shaped regulator. All the connections should be of metal to lessen the chances of fire. In order to have a temperature record it is advisable to place in the room a thermometrograph, the best form of which is made by the Richard Frères, of Paris.

Gas-Pressure Regulator.—The best results with any form of thermo-regulator are obtained when the gas pressure is constant, or nearly so. When the variation is considerable it is advisable to pass the gas through a pressure regulator before it reaches the thermo-regulator. There are several forms of apparatus for this purpose. The Moitessier regulator is shown in Fig. 5079. It consists of a cylinder *A*, which is filled to the level of *G*, with a mixture of equal parts of glycerin and water. On this is floated the metal shell *B*. The gas is admitted to the interior of *B*, through the tube *K*, the pressure being indicated by the manometer *P*. The gas flows into *B* until it is filled, when it raises it up and shuts off the supply of gas by closing the valve *D*. The pressure on the burner is regulated by the weights placed in the pan *H*, which is connected with *B* by the rod *G*. The amount of pressure on the burner is indicated by the manometer on the left of the apparatus. The burner is connected with the apparatus by means of a rubber tube attached to *I*, and the height of the flame is regulated by the stopcock *M*.

A cheaper and more simple regulator is that devised in Novy's laboratory by Murrill and shown in Fig. 5080. The gas passes into a cylinder which floats in liquid petroleum and leaves by two tubes at the bottom, one of which is connected with the thermo-regulator, the other with a manometer. The cylinder is weighted so as to give the desired pressure to the outflowing gas.

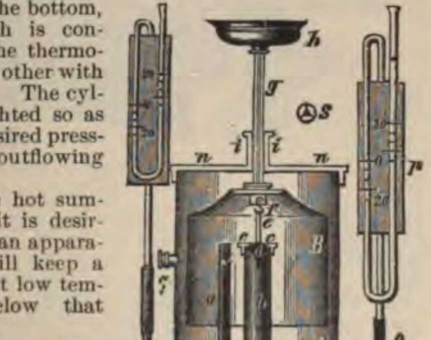

FIG. 5079.—Moitessier's Gas-Pressure Regulator.

During the hot summer months it is desirable to have an apparatus which will keep a fairly constant low temperature, below that which would cause the gelatin cultures to melt. There are incubators constructed for this purpose which furnish a supply of ice-cold water when the temperature rises above a given point. If the temperature drops too low an electric lamp is turned on.

When the temperature of the water as it leaves the ground is about 15° it is possible to use the simple apparatus shown in Fig. 5081. This is made of galvanized iron. The inner box is held in place by means of a couple of stout rods. The water enters at the bottom through the small tube, which stops short on the inside of the outer box. The water then flows under and around the inner box, and eventually reaches at the farther end the wide outflow tube. The end of this is turned up and is provided with a short piece of rubber tubing. By moving this up or down the level of the water in the box can be regulated. By regulating the flow of the water it is possible to maintain a fairly constant temperature in the inner compartment.

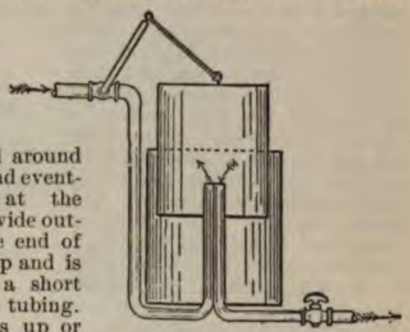

FIG. 5080.—Murrill's Gas Pressure Regulator. Cross-section. (Novy.)

The Methods of Cultivation.—The fundamental basis of bacteriology may be said to be the fact that it is possible to cultivate artificially, and that in pure condition, nearly all of the known forms of bacteria. Until methods had been devised for this purpose it was not possible to determine definitely the part played by any organism either in the ordinary phenomena of fermentation or in the more mysterious processes of disease. To arrive at a demonstration of the causal relation of a given organism to the change which it is supposed to induce it is necessary to do two things: First, the organism must be isolated in pure culture; and second, the pure culture, once obtained, must be maintained by transplantation. The pure culture thus kept up through a series of transplantations, or generations as they are called, can then be tested upon animals to see if it will reproduce the disease; upon suitable media to ascertain if it will cause the kind of fermentation, the pigment, or the light which it is supposed to produce.

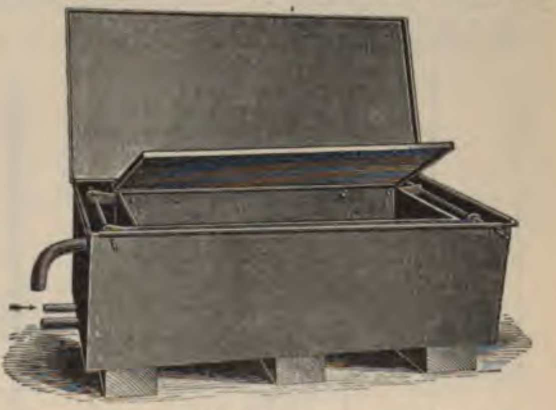

FIG. 5081.—Novy's Low-Temperature Incubator.

By a pure culture is meant one which is derived from a single cell. A given bacterium, small as it is, multiplies by division, and thus gives rise to two new individuals. These in turn grow and divide, yielding four cells. This process is kept up till many millions of organisms constitute the offspring of a single cell. Inasmuch as the division of bacteria is very rapid under favorable conditions, many dividing every half-hour, it follows that in a few hours a visible growth may be seen where at the beginning but a single cell was present. If the medium in which they are growing is liquid, it will usually become cloudy because of the disseminated bacteria.

The early methods of cultivation, as employed by Pasteur, made use of liquid media. Under these conditions it was exceedingly difficult to obtain pure cultures, and indeed it was largely a matter of chance and patience. Suppose that a given liquid contains two kinds of bacteria; in order to separate these so as to have a single cell as a starter for the pure culture it would be necessary so to dilute the liquid that in all probability a drop, or a cubic centimetre, would contain but one cell. This small quantity would then be taken and transferred to a sterile medium, and in this way it would be possible to obtain presumably pure cultures. Failure, however, was necessarily frequent and the element of doubt always remained.

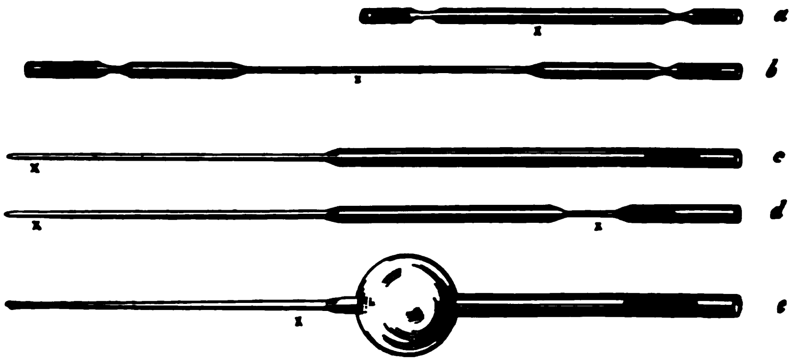

FIG. 5084.—Pasteur Pipettes, showing Method of Preparation. (Novy.)

The introduction of the nutrient gelatin by Koch made it possible to secure pure cultures with the greatest of ease. All that was necessary was to inoculate the liquefied gelatin with the mixture of bacteria, and after thorough agitation so as to separate each cell from its neighbor, to pour the liquid on to the surface of a sterile plate. The gelatin now solidifies and imprisons, as it were, the separated cells. Each of these now multiplies and reproduces its kind; eventually, in the course of a day or two, a small growth, perhaps of the size of a small pinhead, appears. This is called a colony, and since it is derived from a single cell it constitutes a pure culture. Such is the principle of the dilution method for obtaining pure cultures. The isolation once accomplished, all that is necessary is to transplant the colony to sterile culture media so as to keep up the growth.

The transferring of bacteria is usually done by means of a platinum wire. The wire, which should be about two inches long and fairly stiff, about No. 21 in size, is fused into the end of a glass rod. According to the object in view it is either straight, bent, or is provided with a loop as shown in Fig. 5082.

At times a bunch of very fine platinum wires attached to a holder, the so-called Kruse's brush, is used to spread the material over the surface of the media. A glass rod bent at right angles is also very useful for this purpose. The Roux spatula of nickeled steel was first employed for the purpose of transplanting bits of diphtheritic membrane to the culture tube. A similar spatula made of thick iron wire is extremely useful for transferring moulds and compact growths, such as that of actinomyces. The Nuttall platinum spear is particularly useful for transferring bits of tissue, blood, etc., to the nutrient media. These two instruments are shown in Fig. 5083.

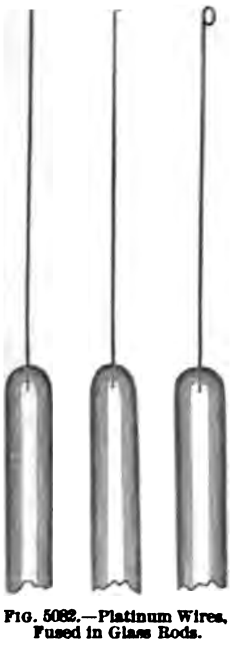

FIG. 5082.—Platinum Wires, Fused in Glass Rods.

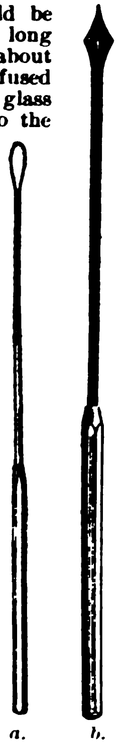

FIG. 5083.—*a*, Roux spatula; *b*, Nuttall's platinum spear.

The transferring of liquids, in large or in small quantities, can best be done by means of drawn-out glass tube pipettes, as is practised by the Pasteur School. This technique is at once simple and invaluable. The preparation of these pipettes will be understood from Fig. 5084.

The glass tubing, which has a diameter of about 8 mm., is cut up into lengths of about twelve inches. By means of the blast lamp a slight constriction is made at about two inches from each end. This serves to prevent the cotton plug from falling down, and also tends to keep the liquid from reaching the cotton. The ends of each tube are then carefully rounded out in the flame. A piece of cotton is then pushed into the end of each tube. The tubes thus prepared (Fig. 5084, *a*) are then sterilized in the dry-heat oven, after which they may be stowed away for future use.

Whenever it is desired to make a pipette, one of these tubes is heated in the middle in a blast flame, and when the glass has thoroughly softened, the two halves are slowly drawn apart. A relatively wide, thick-walled capillary, about sixteen inches long, is thus obtained (Fig. 5084, *b*). This is then sealed in the flame in the middle, and the result are two pipettes. For transferring larger quantities of liquid a bulb is blown in the pipette (Fig. 5084, *e*). This is made by directing a narrow blast flame against the tube, which is at the same time rotated. As the glass softens the ends are slightly pushed together, so as to form a thick ring of glass. This is repeated once or twice. Finally a large blast flame is turned on, and when the thickened glass is perfectly soft, the end is brought into the mouth and the bulb is blown. The glass should be rotated during this operation, and in fact in all work of this kind.

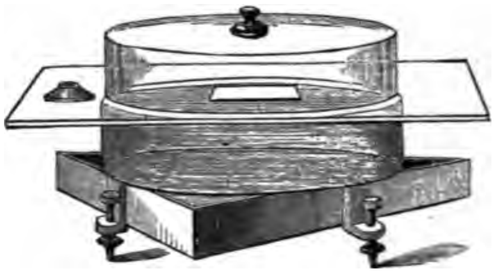

FIG. 5085.—Koch's Levelling Apparatus.

To use a pipette, the mouth end should first be rolled for a few seconds in a flame so as to insure sterility; the capillary end is then scratched with a file and the tip is broken off, after which the capillary is flamed. As soon as the tube has cooled, which fact can be ascertained by blowing through the pipette against the back of the hand, it is ready for use. The closure of the pipette when it is filled with the liquid is effected by means of the tongue

The great value of the pipette lies in the fact that it can be made in a few minutes, and can be used to transfer liquids from one tube to another, for drawing blood from the heart, fluids from the cavities, etc. It is indeed even more useful than a platinum wire.

Plate Cultures.—Solid media, such as gelatin or agar, either plain or modified, are employed for this purpose. The starting-point in this method were the slide cultures used by Koch in his early investigations. The liquefied gelatin was poured upon the surface of sterile glass slides, which were levelled and kept cool by means of the apparatus shown in Fig. 5085. The lower dish was filled with ice water and the whole was set true by the aid of a small spirit level. A series of parallel streaks was then made on the solid gelatin by means of a platinum wire, which was dipped in the material to be planted. A number of slides were thus made, after which they were stacked on glass benches (Fig. 5086), and placed in a moist chamber to develop (Fig. 5087). The first streak, on account of the large number of organisms planted, would probably yield a continuous solid growth. The next streak would have fewer germs, and the succeeding ones still less until eventually only single germs would be deposited, separated by an appreciable distance from the following ones. Wherever a single organism was deposited, as a result of multiplication, a colony would soon make its appearance. (See Plate LXI.)

The slide method was soon improved by substituting larger glass plates (10 × 13 cm.). Instead of making streak dilutions as just given, the gelatin was liquefied, inoculated, and poured out upon the sterile plates, which were cooled on the plating apparatus. This method of plating may be used when the special Petri dishes, ordinarily employed, are not obtainable. The fact that the method required a lot of apparatus, slides, slide-box, levelling apparatus, ice, moist chamber, etc., as well as the fact that contamination from the air and from the dripping of the superposed plates was unavoidable, led Petri to introduce the modification which has almost entirely supplanted the older method.

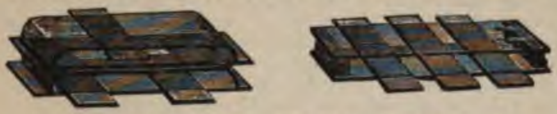

FIG. 5086.—Glass Benches and Culture Slides.

Gelatin Petri Plates.—In this method, as in the preceding, the gelatin is first melted by immersion in warm water for a few minutes. By means of a sterile, looped, platinum wire a small quantity of the material to be examined is transferred to a tube of liquefied gelatin, marked 1. By means of the wire the material is thoroughly mixed with the gelatin. Another tube, marked 2, is then placed beside the first, from which three loopsful of gelatin are carried over to tube 2, with the contents of which they are well mixed (Fig. 5088). A third tube, marked 3, is then placed beside number 2, and three loopsful of gelatin are transferred from tube 2 to tube 3. It is evident from this procedure that even if the first tube received a million germs the second tube would contain only a small fraction, and the third tube would contain still less. The platinum wire must of course be sterilized whenever an inoculation is made into a new tube.

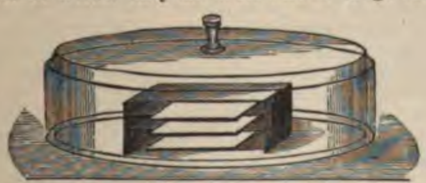

FIG. 5087.—Moist Chamber with Stacked Plates.

A number of Petri dishes (Fig. 5089), which are 10 cm. in diameter and 1 cm. high, are previously sterilized by heating in a dry-heat oven for one hour at 150°, or for a few minutes at 200°, and allowed to cool. To pour the plate, the cotton is removed from one of the tubes, and the open end is rolled for a few seconds in the flame so as to sterilize it. In a few seconds the end of the tube becomes cool, after which the contents are poured out into the Petri dish. The lid of the latter is removed just sufficiently to allow the gelatin to be introduced. By tilting the gelatin is then spread all over the bottom of the dish. The latter is then set aside in a cool place for the gelatin to set. With a good gelatin this will take place even in the ordinary room within a few minutes. The remaining gelatin tubes are poured in the same manner. Each plate should be numbered to correspond to the tube from which it was made. They should be marked also with the date and the kind of material used. A Faber's colored wax pencil is used for this purpose.

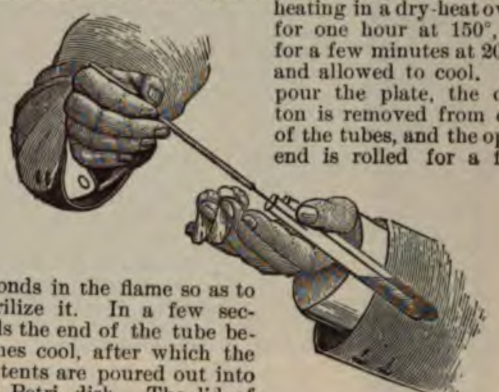

FIG. 5088.—Method of Holding the Tubes when Making Dilutions.

Agar Petri Plates.—Inasmuch as gelatin melts at about 25° C. it follows that the method just given cannot be used when the organism requires the temperature of the incubator. In such cases it is necessary to resort to the use of agar. The nutrient again is first melted by heating in a water-bath at 100° C. The flame is then turned out and the tubes are allowed to cool in the water-bath until a temperature of about 45° is reached. The agar solidifies at about 40°, and consequently the dilution must be made rapidly and the plates poured before the point is reached. Dilution cultures are made in the same way as just given for gelatin. The three agar tubes are then poured out into the corresponding sterile Petri dishes. The agar promptly solidifies, and for that reason the spreading of the agar over the bottom must be hastened. The agar plates are then set aside to develop either at the temperature of the room or at that of the incubator.

FIG. 5089.—Petri Dish for Plating.

Esmarch Roll-Tube Culture.—This modification of the plate method does away with the use of any special container other than the test tube. The dilutions in gelatin are made in the usual way. According to the original directions the cotton plug was cut off short, and the end of the tube was covered with a close-fitting rubber cap. The tube was then immersed and rotated in an almost horizontal position in ice water. The gelatin solidified in an even film over the inside of the test tube (Fig. 5090).

A more convenient way of rolling the tubes was devised by Booker. With the aid of a large test tube filled with warm water a groove is melted into a block of ice. The gelatin tubes are then rolled in this groove until the gelatin solidifies in a smooth, even film. Nuttall has modified this procedure by replacing the ice block with a marble block provided with grooves for the test tubes. Running tap water serves to cool the tubes.

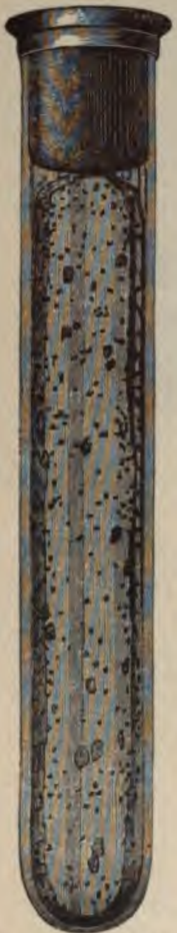

FIG. 5090.—Esmarch's Roll Culture.

If the tubes are not rolled smoothly they can be softened by gentle warming and rerolled. One advantage of this method lies in the fact that desiccation can be retarded more than with the other methods. Air contamination is likewise diminished. On the other hand, the presence of a few liquefying bacteria may spoil the tube. The Esmarch roll tubes should be kept in a cool place to prevent melting. When the colonies develop they may be examined by placing the tube on the stage of the microscope. To transplant the colonies a platinum wire, provided with a hook, as shown in Fig. 5082, should be used.

Shake Cultures. — Dilutions are made in gelatin or agar as heretofore described. The tubes are then solidified in an upright position and allowed to develop. If it is desired to transplant a given colony the test tube should be scratched with a diamond at about the level of the colony. On touching the scratch with a hot rod, the crack can be led around the tube, after which the two parts can be separated. By means of a sterile knife the medium can be cut and the colony exposed. In the case of agar the entire cylinder of agar can be forced out of the tube into a sterile dish by the cautious application of a flame to the lower end of the tube.

The method offers a convenient means of determining whether or not the organism planted generates gas. If such is the case gas bubbles will make their appearance in the medium. As will be seen later this method is also useful in connection with the cultivation of anaerobic bacteria.

Streak Cultures.—This procedure, which is essentially the same as that used by Koch in his slide cultures, is very frequently made use of at the present time. Thus, sterile gelatin or agar may be poured into sterile Petri dishes, and after the material has solidified a series of parallel streaks may be made with an infected wire. The Kruse platinum brush may be used to spread the organisms over the surface. A narrow glass rod, bent and flattened at the end, has been used for spreading gonorrhœal pus over plates. Cotton swabs are used for the same purpose in the case of diphtheria.

As in the case of the Esmarch roll tube, the Petri dish may be omitted in this method. In that event the gelatin or agar is melted and allowed to solidify in an inclined position. The streaks are then made on the surface of the inclined medium. Potato tubes are inoculated in the same way. (See Plates LX. and LXI.)

To obtain perfectly isolated colonies by this method the same wire should be used to make parallel streaks on each of four or five tubes. When the colonies develop transplantations can be made by means of a bent wire.

Hanging-drop Cultures.—A concave or well slide, shown in Figs. 5105 and 5106, is used. The cover glass must first be sterilized by passing it several times through a flame. A large drop of sterile bouillon is then placed in the centre, and this is then inoculated with the germ to be studied. The slide with a ring of vaseline is then inverted and brought down upon the cover-glass, after which the preparation is turned over. Care must be taken to see that the vaseline closure is perfect. This method of cultivation is used to study the multiplication of the bacteria under the microscope.

Hanging-block Cultures.—In order to be able to study the morphology and the multiplication of the diphtheria bacillus to better advantage than that afforded by the hanging drop, Hill devised the following procedure: Melted nutrient agar is poured into a Petri dish to a depth of about one-eighth to one-quarter inch. When cool, a block of agar is cut out, about one-quarter to one-third inch square, and of the thickness of the agar layer in the dish. The block is placed, under surface down, on a slide and protected from dust. A suspension of the growth to be examined is then made in sterile water or a bouillon culture is used. The suspension is spread over the upper surface of the block as if making an ordinary cover-slip preparation. The slide and block are then set aside in the incubator at 37° for five or ten minutes, to dry slightly. A clean sterile cover slip is then placed on the inoculated surface of the block in close contact, avoiding large air bubbles. The slide is then removed from the under surface of the block, and the cover slip is inverted so that the agar block is uppermost. With the aid of a platinum wire a drop or two of melted agar is run along each side of the agar block, to fill the angles between the sides of the block and the cover slip. This seal hardens at once and prevents slipping of the block. The preparation is again placed in the incubator for five or ten minutes to dry the agar seal. Finally the preparation is inverted over a moist chamber or suitable well slide. The cover slip is sealed in place with white wax or paraffin. Vaseline cannot be used because it softens at 37°. The "hanging block," thus prepared, is examined on a warm stage or in the incubator room.

Transplantation of Colonies.—The entire object of making plate culture by any one of the several methods given is to obtain single isolated colonies, which can be transplanted to other media and the organism present can then be studied in perfectly pure condition. The colony as indicated is presumably derived from a single cell, and consequently is a pure culture. The transplantations or sub-cultures can be made to gelatin, agar, serum, bouillon, milk, etc. When the colonies are on a plate or in a Petri dish a straight wire is used. The plate is first carefully examined under the microscope, and a colony is selected which is clearly single. If possible it should be the only one in the field of the No. 3, or one-third inch objective. The farther apart that the colonies are the less likely are they to intermingle. As originally directed, the colonies were touched under the microscope by a sterile platinum wire, and in this way a few of the bacteria were removed. Care had to be taken that the wire did not touch the objective or any other part of the gelatin. This operation of "fishing," as it was called, obviously required considerable practice and care. An equally good procedure is to pick out the desired colony under the microscope. The tube of the microscope is then raised, and the point of the sterile wire is brought down so that it cuts the colony and nothing else. The tube is then again lowered and the site of the colony examined to make sure that nothing but the one colony was touched. If such is the case the wire is then used for the sub-culture.

Stab Cultures.—A tube of solid gelatin is taken, the cotton plug is seized by the right little finger and removed. The mouth of the tube is then flamed, after which the wire, laden with the bacteria, is inserted and carefully passed down the centre of the gelatin. The organisms are thus planted along the line of inoculation. The cotton plug is replaced and the tube is labelled and set aside. The form of the growth is then noted from day to day, also the presence of gas, liquefaction, pig-

ment, etc. The characteristics of the stab cultures are of the very greatest importance in the identification of bacteria. If the gelatin is old and partially dried, the passage of the needle is likely to cause a split in the medium. This can be avoided by melting and resolidifying the gelatin. (See Plates LX. and LXI.)

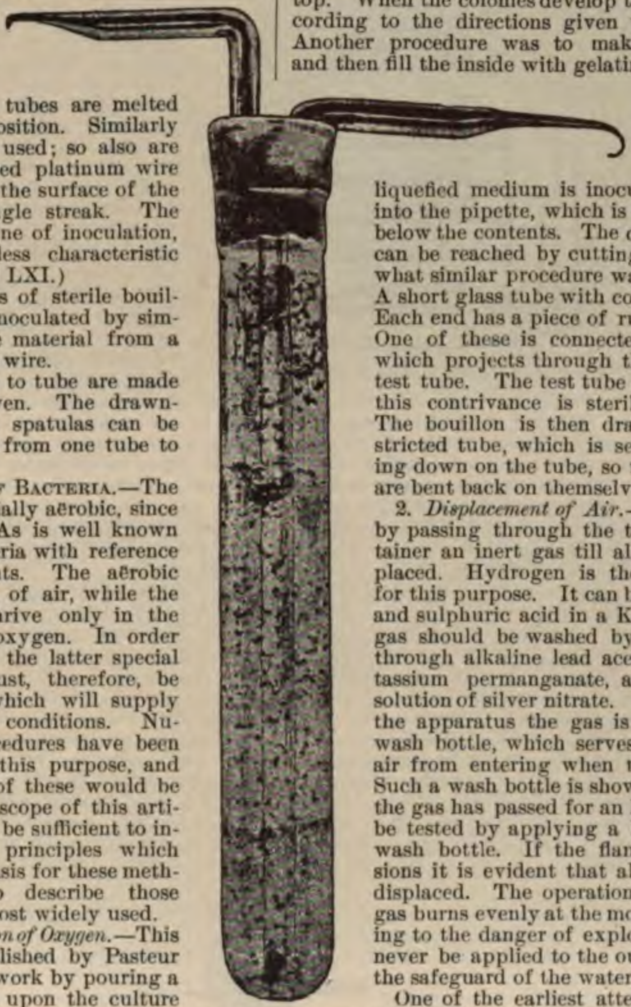

FIG. 5092.—Fraenkel's Modification of Liborius Tube for Anaërobes.

Streak Cultures.—These are also known as "smear cultures." The gelatin or agar tubes are melted and solidified in an inclined position. Similarly solidified blood serum is also used; so also are the potato tubes. The infected platinum wire is drawn along the middle of the surface of the medium by making one single streak. The growth develops along the line of inoculation, and spreads in a more or less characteristic manner. (See Plates LX. and LXI.)

Liquid Cultures.—The tubes of sterile bouillon, milk, serum, etc., are inoculated by simply introducing some of the material from a colony by means of the sterile wire.

The sub-cultures from tube to tube are made in the same way as just given. The drawn-out glass tube pipettes and spatulas can be used to transfer the material from one tube to another, or to flasks.

ANAËROBIC CULTIVATION OF BACTERIA.—The methods just given are essentially aërobic, since there is free access of air. As is well known there are two classes of bacteria with reference to their oxygen requirements. The aërobic bacteria live in the presence of air, while the anaërobic thrive only in the absence of oxygen. In order to cultivate the latter special methods must, therefore, be employed which will supply the needed conditions. Numerous procedures have been devised for this purpose, and to give all of these would be beyond the scope of this article. It will be sufficient to indicate the principles which serve as a basis for these methods, and to describe those which are most widely used.

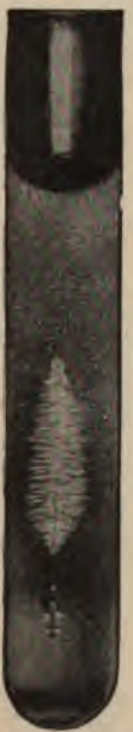

FIG. 5091.—Liborius Deep Stab Culture, showing Growth of the Tetanus Bacillus.

1. *Exclusion of Oxygen.*—This was accomplished by Pasteur in his early work by pouring a layer of oil upon the culture fluid. This served to exclude the air and allowed the bacteria to develop. Koch obtained anaërobic conditions by covering the surface of the gelatin plates with a thin sheet of mica. Others have done the same with glass plates.

The Liborius method of cultivation in deep layers falls under this head. It is simple and is constantly used. Ordinary stab cultures are made in the suitable media, preferably glucose agar. Another tube of agar is liquefied, cooled to about 50°, and the contents of this are then poured on top of the stab culture. Care must be taken to flame the mouths of both tubes so as to avoid contamination. The upper layer of agar serves to keep out the air. The cultures can be prepared equally well by employing agar or gelatin tubes filled with the medium to a depth of about two inches. After the stab is made the line of puncture closes up itself, and the growth then develops in the lower part of the tube, as shown in Fig. 5091.

Isolated colonies can also be obtained by this method. The liquefied medium is inoculated and dilutions are made as for shake cultures. The tubes are then solidified, and if necessary an additional layer of medium is poured on top. When the colonies develop they can be reached according to the directions given under shake cultures. Another procedure was to make Esmarch roll tubes and then fill the inside with gelatin or agar.

The drawn-out glass tube pipettes (Fig. 5084) have been used by Roux for this same purpose. The liquefied medium is inoculated and drawn up into the pipette, which is then sealed above and below the contents. The colonies which develop can be reached by cutting the glass. A somewhat similar procedure was devised by Wright. A short glass tube with constricted ends is used. Each end has a piece of rubber tubing attached. One of these is connected with a glass tube, which projects through the cotton plug of the test tube. The test tube contains bouillon, and this contrivance is sterilized and inoculated. The bouillon is then drawn up into the constricted tube, which is sealed by simply pushing down on the tube, so that both rubber ends are bent back on themselves.

2. *Displacement of Air.*—This is accomplished by passing through the tube or a suitable container an inert gas till all the air has been displaced. Hydrogen is the least injurious gas for this purpose. It can be generated from zinc and sulphuric acid in a Kipp's generator. The gas should be washed by passing successively through alkaline lead acetate, six per cent. potassium permanganate, and finally through a solution of silver nitrate. After passing through the apparatus the gas is sent through a small wash bottle, which serves as a valve to prevent air from entering when the current slows up. Such a wash bottle is shown in Fig. 5093. After the gas has passed for an hour or more it should be tested by applying a light as it leaves the wash bottle. If the flame burns with explosions it is evident that all the air has not been displaced. The operation is continued until the gas burns evenly at the mouth of the tube. Owing to the danger of explosion the light should never be applied to the outflowing gas without the safeguard of the water valve.

One of the earliest attempts at making tube cultures by this method was that of Liborius. He made use of a special test tube with a delivery tube fused into the side. After inoculation of the liquid medium gas was passed through, and finally the neck of the test tube, as well as the end of the delivery tube, were sealed in the flame. This method is of only very limited application, and requires much time and is expensive. Fraenkel's modification is a distinct improvement. Ordinary large test tubes are used. These are provided with rubber stoppers and delivery tubes, as shown in Fig. 5092. After the inoculation of the medium and expulsion of the air, the tubes are sealed in the flame. If it is desired to obtain colonies, the tube can be converted into an Esmarch roll tube, as shown in Fig. 5092.

This principle has been adapted in various ways for the purpose of obtaining plate cultures. Kitasato employed a flat bottle, having a tube fused at the lower end. The dilutions were made in the ordinary tubes, after which the material was poured into these flasks, which were connected in series and hydrogen passed through. Finally the ends were sealed by fusing in the flame, while the neck of each flask was closed with a clamped rubber tube. Several modifications of this bottle have been made, but they are little used, since methods were soon perfected whereby it was possible to make Petri plates in hydrogen.

One of the earliest attempts in this direction was that of Blücher, who made use of a funnel which was weighted with lead and inverted over the plates in a larger dish. Air was excluded by means of glycerin water. Hesse inverted a glass vessel in a circular trough filled with mercury. Liborius used a copper bell jar which was compressed against a rubber gasket by means of set screws; others made use of bell jars inverted upon a ground glass surface. In many respects the Botkin apparatus is useful. It is shown in Fig. 5093. It consists of a metal rack on which are placed the Petri dishes. This is set in a large outer dish which contains about an inch of liquid petroleum. A bell jar is inverted over the stand. The inflow and outflow tubes are of rubber stiffened by a copper wire on the inside. After the hydrogen has been passed for a sufficient length of time, the tubes are withdrawn and the apparatus is then set aside.

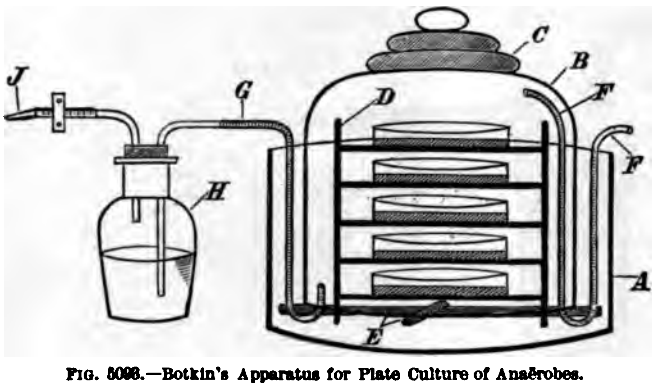

FIG. 5093.—Botkin's Apparatus for Plate Culture of Anaërobes.

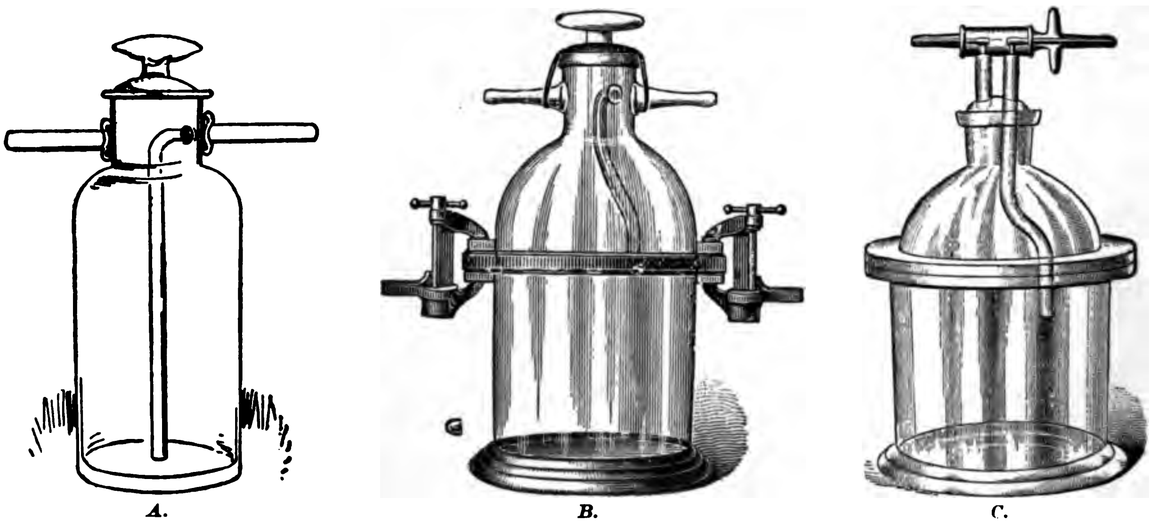
The Novy apparatus shown in Fig. 5094 leaves little to be desired. The hollow stopper has two perforations, one of which is connected with a glass tube which extends almost to the bottom of the bottle. In the case of the plate apparatus the tube may be continued by means of a piece of rubber tubing. A perfect seal is obtained by simply turning the stopper through an angle of 90°.



A. B. C.

FIG. 5094.—Novy Apparatus for Anaërobes. *A*, Bottle for tube cultures; *B*, Jar for Petri plates; *C*, Jar for plates with special stopcock for vacuum culture.

The bottle (Fig. 5094, *A*) is made in two sizes, 8 × 16 and 10 × 20 cm., which dimensions do not include the neck. A piece of cotton should be placed on the bottom.

The ordinary test tubes containing any medium are inoculated in the usual way. The cotton plug is then cut off square, and by means of a pair of crucible tongs the tube is lowered into the bottle. It is advisable, if the cotton plug is very tight, to loosen it up by partially pulling it out. A single jar can be filled in this way with a large number of tubes containing either solid or liquid media. The stopper is then put in place and the apparatus connected with a hydrogen generator. When the gas has passed for a sufficient length of time the bottle is closed by giving the stopper a turn. As will be seen this jar can be used likewise for the pyrogallate method.

The plate apparatus shown in Fig. 5094, *B*, consists of two parts. The inner dimensions of the lower part are 12 × 12 cm. The Petri plates are stacked into this compartment. The flanges are covered with a mixture of beeswax and olive oil (1:4). The two parts are then brought together and a rubber band is slipped over the outer edge of the flanges. Two or three clamps or small vises are now applied. The jaws of these should be covered with a piece of rubber tubing. Gas is passed as in case of the bottle, and at the conclusion of this operation the stopcock is given a turn so as to seal the apparatus.

The other modification (Fig. 5094, *C*) has a special stopper, which enables it to be used for vacuum cultures. It can, however, be employed equally well for hydrogen cultivation. Moreover, both forms of the plate apparatus, as well as the bottle, can be used for the pyrogallate method.

3. *Absorption of Oxygen.*—The most convenient absorbent for this purpose is an alkaline solution of pyrogallic acid. The principle was first utilized by Buchner for tube cultures, as shown in Fig. 5095. The large outer tube is provided with a closely fitting rubber stopper. On the bottom of the tube is placed about a gram of pyrogallic acid and a suitable support. The tube containing the nutrient medium is inoculated in the usual way and placed on this support. Finally 10 c.c. of a ten-per-cent. solution of potassium or sodium hydrate is added from a pipette, as rapidly as possible, and the tube is then quickly closed with the stopper.

As mentioned above, the Novy apparatus can be employed for the pyrogallate method. In the case of the jar a wide tube is introduced which contains about 2 gm. of the acid. After the culture tubes have all been inserted, about 20 c.c. of a twenty-five-per-cent. solution of sodium hydrate is introduced into the pyrogallate tube

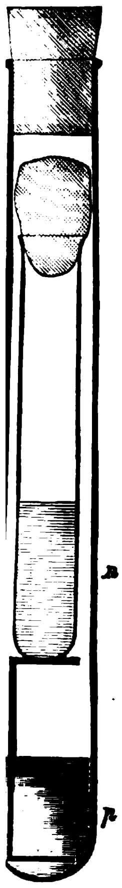
rom a pipette, and the stopcock is then inserted as uickly as possible and turned. In the case of the plate pparatus a crystallizing dish, about 10 cm. in diameter nd about 2 cm. high, is placed on the bottom, and about gm. of pyrogallic acid added. A couple of strips of lass are then placed on top, and on these are stacked the 'etri dishes. Twenty-five cubic centimetres of the strong alkali are introduced in the manner just mentioned, after which the top is put into place, the clamps and the rubber band are applied.



5095.—Buch-
r's Pyrogal-
te Method.

Wright's method will be found to be very useful for occasional cultures. The cotton plug is cut off square and pushed down about 1 cm. into the tube. The plug is made of absorbent cotton. It is then moistened with about 4 c.c. of a strong solution of pyrogallic acid, after which about the same volume of strong sodium hydrate (1:2) is added. The tube is closed as rapidly as possible with a tight-fitting rubber stopper. Obviously, solid pyrogallic acid may be used.

It will be seen that the pyrogallic-acid method is extremely convenient and very simple, requiring a minimum of time and expense. The method is also applicable for the *hanging-drop examination* of anaërobic bacteria. A drop of alkali and of the acid can be placed on the side of the concave slide. After the cover is in place the slide can be tilted so as to bring the two liquids together. A special slide for this purpose was devised by Braatz (Fig. 5096).

The hanging drop is made and placed over the well. The flat flask contains the pyrogallic acid and communicates with the space below the drop. Strong alkali is finally added and the flask is closed with a stopper. Pyrogallic acid can also be employed in connection with Hill's "hanging-block" culture. Another apparatus for anaërobic hanging drops is that of Kühne. It is very serviceable and can be used for either the gas or pyrogallate process.

4. *Exhaustion of Air.*—Pasteur employed U-shaped tubes, from which the air was removed by means of an air pump. Gruber applied the principle to the tube culture. He used a stout glass tube, which was provided with a stop- , through which passed a short glass tube by which nection was made with the air pump. The test tube ; constricted just below the stopper so as to facilitate subsequent sealing process. The tube was filled in usual way with the nutrient medium and inoculat- It was then connected with the pump, and as soon he air was exhausted the tube was sealed at the con- tion. The plate apparatus shown in Fig. 5094, *C*, is nded for vacuum as well as gas or pyrogallate cult- s. It can be used for tube or plate cultures.

Mixed Cultures.—This method of cultivating anaë- c bacteria corresponds to the way in which these or- isms grow in nature. If the anaërobe is planted ther with an aërobe, the latter will consume all the gen in the immediate neighborhood, and as a result anaërobe will grow. Thus, if the tetanus and hay lli are planted at the same time into a tube of bouil- they will both develop. Other aërobic bacteria, as the Bacillus prodigiosus and Proteus vulgaris, be used for the same purpose.

Cultivation in Air.—This of course is apparent er than real. If a tube of glucose gelatin, preferably red with litmus, be inoculated with an anaërobe and set aside in the incubator, an abundant growth will elop (Novy's method). Similarly, when deep stab cultures are made of the anaërobes, it will be found quite frequently that the water of condensation on the top of the medium is cloudy from the growth of the germs. The explanation in the one case is that air is excluded partly by the viscosity of the liquid and partly by the evolved gases. The gas formation accounts for the growth of the germs in the water of condensation. The culture in glucose litmus gelatin is by far the simplest way of growing anaërobes. Moreover, the cultures thus obtained retain their vitality for many years. In some cases the author has recovered cultures from tubes five and six years old.

Collodium Sacs.—This method of cultivating has been used extensively by the Pasteur School for exalting the virulence of bacteria. The underlying idea is to grow the organisms in the peritoneal cavity of an animal, and under such conditions that the waste products of the germs will be removed, an abundant supply of nutrient material furnished, and the germs themselves protected against the action of phagocytes. This is accomplished by enclosing the bacteria in a hermetically sealed sac, the walls of which are permeable to the waste products of the germs and to the soluble proteids of the peritoneal fluid. Several Russian workers have employed for this purpose the inner lining membrane of reeds, but the best procedure is to make the sacs of collodium. Various methods have been devised for the rolling of the sac, but undoubtedly the best and simplest is that perfected in the author's laboratory by Gorsline.

The rolling tube employed for making sacs is about twelve to fifteen inches long, and of any width that may be desired. For ordinary purposes a width of half an inch is sufficient. One end of this tube is rounded off like a test tube, and has a 2 mm. opening at the tip. This opening is first closed with collodium either by touching it with the cork which has been covered with the solution, or the collodium may be applied with the finger. Care must be taken to see to it that the collodium does not get inside of the tube. In a few seconds the layer is dry enough to go ahead.

The collodium used is the United States Pharmacopœia solution, which by exposure to the air has been concentrated by one-third or one-half. It should be perfectly clear, and if not it must be filtered through cotton by the aid of a pump. The collodium can be kept in a glass-stoppered cylindrical vessel, such as is used for the collection of blood. The collodium is inclined till it comes within a few inches of the opening.

The rolling tube, with the opening freshly closed, is dipped in the collodium and rolled several times in the liquid. It may be rolled so that only the lower side of the tube touches the collodium. If the sac is to be very thin it is sufficient to roll the tube but two or three times, after which it is raised from the liquid and rolled in the ether atmosphere in a horizontal position till the collodium has set. If the layer is not thick enough the tube can be returned to the collodium, but care must be taken

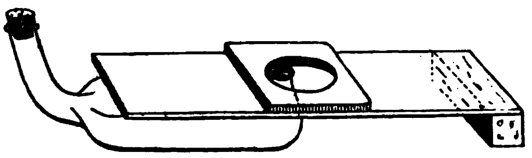


FIG. 5096.—Braatz's Slide for Anaërobic Hanging-drop Examinations.

to avoid the formation of air bubbles. The coated tube is finally rolled in the air until it has reached the proper consistence. This can be ascertained by touching the thickest part with the finger. The collodium layer should be rather firm. The tube is then immersed in distilled water for a minute or two. If the collodium is not sufficiently hard, it will cloud or become milky on contact with the water. It should remain perfectly clear, and when finished a thin sac placed in water is almost invisible.

To detach the sac the tube is filled with distilled water, and by blowing into the open end the water can be forced through the opening below and upward between the sac and the tube. By slight manipulation with the fingers the detachment can be effected readily on all sides. The free end is then trimmed square, after which the sac is placed in distilled water, where it remains until it is ready to be attached to the glass tube.

An ordinary test tube having a diameter slightly less than the sac is constricted in the blast flame at about two inches from the end. A scratch is then made, about a half an inch below the constriction, with a diamond, and with the aid of a hot rod the end is removed. The resulting tube has the form shown in Fig. 5097, *a*. The cut end should be rounded in the flame so as to remove the sharp edge.

The inside of the neck of the sac is dried by means of filter paper, after which the end of the tube is inserted. This can be done more easily if the end of the tube is previously dipped in alcohol. The next step, that of shrinking the sac upon the tube, is very important and requires care. Most of the shrinking is done by rotating the tube, in a horizontal position, some distance above a small spare-flame burner. In this way the collodium can be made to contract down upon the glass, but the operation must be done slowly and at some distance above the flame, otherwise there is danger of igniting the sac. The adhesion is rendered more complete by the application of a hot glass rod. Finally a silk thread is wound as closely as possible over the glass neck, and this in turn is covered with a layer of collodium. The sac now has the appearance shown in Fig. 5097, *b*. The finished sac is now filled with distilled water and placed in a test tube on foot, which also contains water (Fig. 5097, *c*), and the whole is sterilized by steaming in an autoclave for half an hour at 110°.

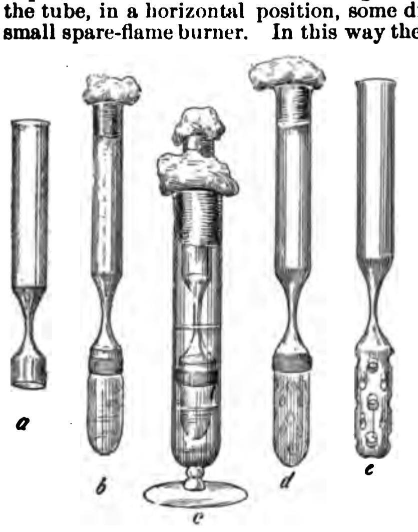

FIG. 5097. — Preparation of Collodium Sacs. (Novy.)

When the sac is to be used, the water is removed from the inside by means of a drawn-out pipette and refilled in like manner with bouillon which has been inoculated with the organism to be tested. The threaded part is then wrapped in a piece of sterile filter paper, for convenience in handling, and the constriction is sealed in a sharp-pointed flame. The sealed sac is then placed in a sterile test glass.

The rabbit or guinea-pig which is to receive the sac is now attached to a holder and the hair is removed from the abdomen. The field of the operation is thoroughly washed with lysol or mercuric chloride. After the animal is anæsthetized an incision is made in the abdominal wall, and through this the sac is introduced into the peritoneal cavity. The incision is then sewed up and covered with cotton and a little collodium.

The sac is allowed to remain in the animal for a few days or even for several months. To remove it the animal is killed with gas. The sac is freed from the adhesions and transferred to a sterile test glass with the glass end downward. By means of a hot rod an opening is burned into the end of the sac, and through this the contents are removed by means of a drawn-out tube pipette. When large sacs are to be inserted into an animal it is advisable to strengthen these by placing within a perforated glass tube as shown in Fig. 5097, *e*, *f*.

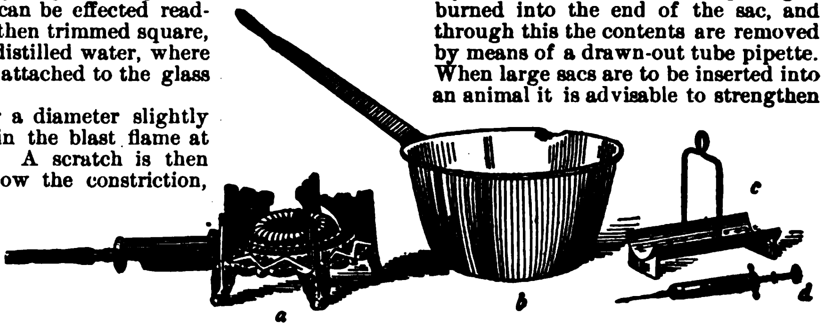

FIG. 5098.—Syringe Holder and Sterilizing Pan. (Novy.)

The collodium sacs can be used not only as just described, but also with marked advantage for dialyzing experiments. For this purpose the sacs can be made an inch or more in diameter and twelve or fifteen inches long. The thin collodium membrane is considerably more permeable than parchment paper.

INOCULATION OF ANIMALS.—According to the nature of the experiment these are made with pure or impure cultures of bacteria, or with the chemical products elaborated by them. The use of impure material is met with in diagnostic work. Thus in suspected glanders the discharge is introduced into animals in order to ascertain if the bacillus of glanders is present. The same is often done in tuberculosis, pneumonia, bubonic plague, anthrax, tetanus, rabies, etc. In all these experiments the animal serves as a plate, since it eliminates all the saprophytic bacteria which may be present in the original material and allows the disease-producing ones to develop in pure or almost pure cultures. The inoculation with pure cultures is made to test their identity, to study their effects upon animals, and to ascertain the diverse means of infection, and for purposes of immunization. The inoculation with the chemical products serves to ascertain the presence of poisonous substances, or to produce vaccines or antitoxins.

The inoculations may be made with a fine needle or lance, but more often with the aid of a syringe. The drawn-out glass tube pipette is also used as a means of introducing infectious material. The syringe used varies with different workers. The Germans are especially favorable to the Koch syringe, which consists of a glass cylinder, graduated, the narrow end of which connects with the needle while the upper end fits into the metal collar of a rubber bulb. The advantage claimed is that the cylinder and needle can be effectively sterilized by dry

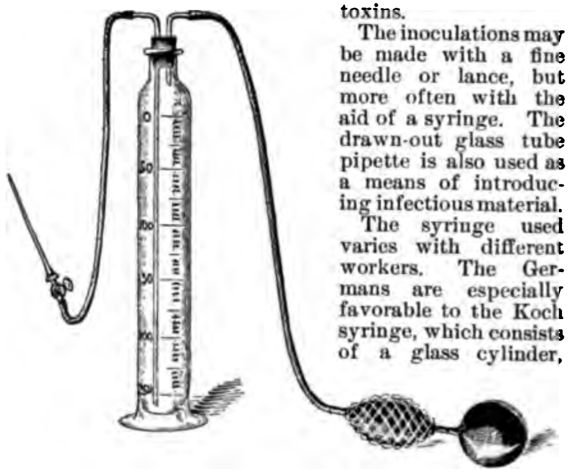

FIG. 5099.—Graduated Cylinder for Injecting Liquids. (Novy.)

heat. As a matter of fact the Koch syringe is extremely inconvenient and unsatisfactory, and equally good results with less time and annoyance are obtainable with the ordinary hypodermic. The latter of course must be sterilized by boiling in water for ten or fifteen minutes. A convenient holder for the syringe is shown in Fig. 5098.

When large quantities of liquids are to be introduced, as when injecting horses with diphtheria toxin in the preparation of antitoxin, an apparatus similar to that shown in Fig. 5099 can be used.

The necessary instruments, such as knives, scissors, needles, etc., are sterilized by boiling in water, or better in a saturated solution of borax. A very convenient sterilizer for this purpose is that shown in Fig. 5104.

In all operations the animal must be secured in some way or another. Various kinds of holders have been constructed for this purpose. That of Latapie, shown in Fig. 5100, is very convenient, and is to be preferred to the ordinary models. It can be used for guinea-pigs, rabbits, birds, etc.

The Voges holder, shown in Fig. 5101, is useful for taking temperatures and for injecting small animals. A good substitute can be made by using a glass cylinder.

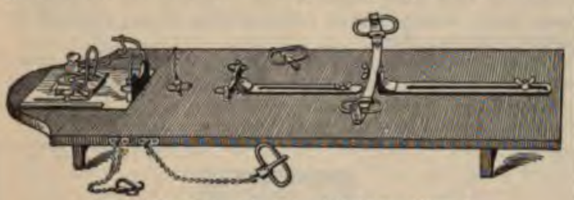

FIG. 5100.—Latapie's Animal Holder. (Novy.)

Special holders have been devised for rats and mice. These, however, can be handled best by means of a pair of compression or artery forceps. The animal is seized by the nape of the neck with the forceps, which are then transferred to the left hand. The tail and the hind legs are also held by this hand. The animal in this way is put upon the stretch, and the inoculation can then be made with the right hand. Even full-grown wild rats can be handled in this way without the help of an assistant.

After inoculation the animals are placed in special jars or cages. The ordinary glass battery jars, provided with a galvanized wire top, weighted with lead, serves to confine rats and mice, and can even be used for guinea-pigs (Fig. 5102). If the animals are inoculated with a very dangerous organism, such as the pest bacillus, it is advisable to place the jar inside of a ten-gallon crock. In special cases, as in animals infected with trypanosomes, bubonic plague, etc., it is well to cover the cage with a piece of mosquito netting as a safeguard against insects spreading the infection.

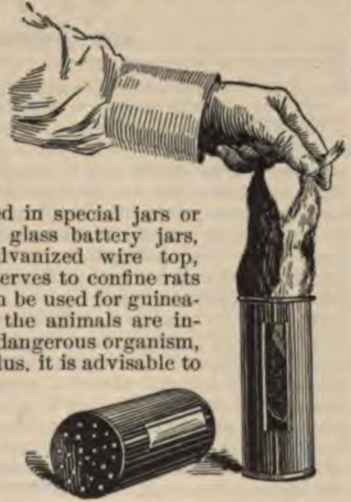

FIG. 5101.—Voges' Holder for Small Animals. (Novy.)

Guinea-pigs, rabbits, and the like can be kept in the Vaughan cage shown in Fig. 5103. The cage proper is 30 cm. high, 38 cm. deep, and 54 cm. wide. The feet are 12 cm. high.

1. *Cutaneous Application.*—Ordinarily bacteria do not penetrate the unbroken skin or mucous membrane. The direct application of some organisms, even in the absence of any known lesion, leads to infection. This is the case when the virus of the foot-and-mouth disease or the bacillus of plague is brought into contact with the mucous membrane. The pus germs, when rubbed into the skin by the aid of vaseline, may cause infection.

2. *Subcutaneous Application.*—For this purpose the hair is removed from the region where the inoculation is to be made. The place is then rubbed with a disinfectant. In the rat this is usually on the back, at the root of the tail; in the guinea-pig it is on the side. A nick is made with sterile scissors, and then with a narrow scalpel or spatula a pocket is made under the skin. A piece of tissue, a bit of earth, blood-laden wire, etc., is then introduced into the opening, which if made small requires no special closure.

3. *Subcutaneous Injection.*—The suspended material is introduced under the skin by means of a syringe. The hair should first be clipped close and the place of inoculation touched up with a disinfectant.

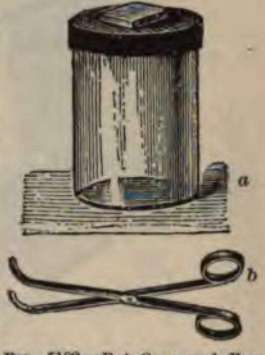

FIG. 5102.—Rat Cage and Forceps. (Novy.)

4. *Intravenous Injection.*—In the case of the rabbit this is easily done. The marginal branch of the posterior auricular vein is selected, although it may appear to be narrower than the needle. The hair may be removed and the surface of the ear rubbed freely to stimulate circulation. A clamp is then applied at the base of the ear so as to distend the vein. The needle is then inserted at a very slight angle to the vein. In other animals the jugular can be exposed and the injection made without any difficulty. In the preparation of preventive sera the culture or toxin is often injected into the jugular of a horse. A trocar is first introduced into the jugular, and this is then connected with the cylinder containing the liquid to be injected (Fig. 5099).

5. *Intraperitoneal Injection.*—This procedure is very commonly resorted to. The skin over the abdomen should be raised and the needle of the syringe is then introduced into the cavity. In the case of the horse, while the animal is standing, a trocar is introduced through the skin at a point a few inches anterior to the crest of the ilium.

6. *Intrapleural Injection.*—The needle is introduced into the right pleural cavity, care being taken to prevent any injury to the lung or to the heart. Large amounts of liquid cannot be tolerated by the animal.

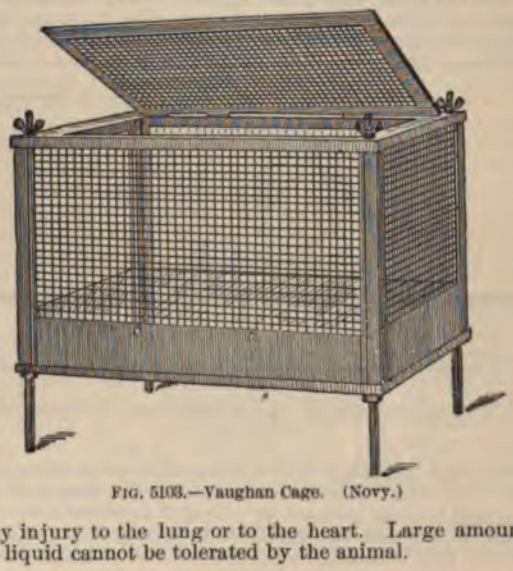

FIG. 5103.—Vaughan Cage. (Novy.)

7. *Intracranial Injection.*—This method was introduced by Pasteur as a means of surely infecting animals with rabies. The procedure is followed out when inoculating animals either for diagnosis or for the purpose of preparing the vaccine for hydrophobia. It is usually practised on rabbits and guinea-pigs. The skin from between the ears forward is shaven clean and disinfected. An incision about an inch long is then made. The Pasteur School apply a hand trephine, and make an opening into the skull. A small trephine, operated by a dental engine, is much more convenient. In the absence of either an opening may be made into the skull with a stout scalpel. By means of a hypodermic syringe a few drops of the brain or cord suspension are then introduced under the dura. At times the injection is made into the brain proper, in which case it is spoken of as *intracerebral*. After the injection a suture or two is applied, and the wound is covered with collodium and cotton.

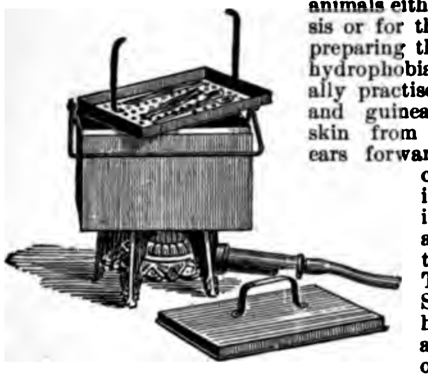

FIG. 5104.—Instrument Sterilizer. (Novy.)

8. *Intra-ocular Injection.*—Cocaine is first applied to the eye, after which this is fixed with forceps and the material injected into the anterior chamber. If desired, an opening can be made with a cataract knife or narrow scalpel and the solid material can be introduced in this way.

9. *Injection into the Lymphatics.*—This is usually made by introducing the material into the testicles.

10. *Respiratory Infection.*—While the preceding methods may be looked upon as wound inoculations, this concerns itself as nearly as possible with duplicating the natural infections along the respiratory tract. The direct method consists in causing the animal to inhale the finely divided material, which can be readily done by means of an atomizer. Another procedure may be called the *intratracheal* injection. This is carried out by making an opening into the trachea, and through this introducing the infectious agent.

11. *Alimentary Infection.*—Since water and food serve to introduce the pathogenic agent of many diseases into man and animals, it is necessary at times to resort to a similar method of infection. The animal may receive the infectious agent in water, milk, or in solid food. Thus bread may be soaked in a bouillon culture of the organism. At other times it may be necessary to introduce the material into the stomach by means of a rubber tube. In order to prevent the animal from biting the tube, it is well to pass it through a perforated cork or plug of soft wood. Under exceptional conditions a laparotomy may be made and the material injected into the intestines. This is spoken of as the *intraduodenal* injection.

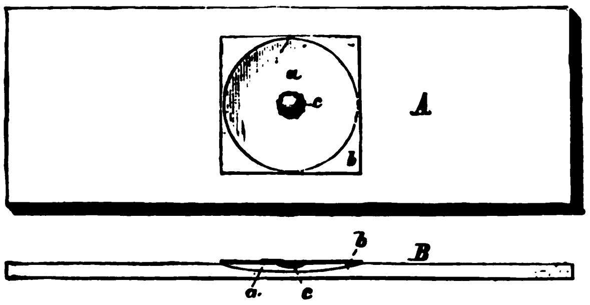

FIG. 5105.—Concave Slide showing Hanging Drop. *A*, Surface view; *B*, side view.

Observation and Autopsy of Infected Animals.—The matter of suitable caging of animals has already been touched upon. Attention may be called to the need of daily observations of the infected animals, so as to note the symptoms manifested. The animals must have plenty of food and drink, and must be kept in as clean a condition as possible. Their weight and temperature should be taken daily, for in this way the best information can be gained as to the physical condition of the animals.

When the animal dies it should be autopsied at once, or else it must be put aside in an icebox. The need of immediate examination is shown in some of the trypanosomatic infections, as nagana and caderas, where the organism may disappear from the blood within an hour or so after death. Moreover, delayed examination may lead to the invasion of the organs of the cadaver by the intestinal bacteria, in which case the search for the specific germ is rendered more difficult, if not impossible.

The animal is prepared for autopsy by being placed on its back and tacked down on a board. A convenient board of this kind is one which is about 34 by 54 cm., and has a raised border. The cracks, if any, should be filled with paraffin.

After the animal is laid out, the hair should be thoroughly moistened with mercuric chloride solution. The necessary instruments can be sterilized in a copper sterilizer, such as is shown in Fig. 5104. In the absence of such an arrangement the instruments may be sterilized by heating directly in the flame, but this, of course, injures them. A searing iron, several drawn-out pipettes and sterile dishes, as well as the necessary media, should be conveniently on hand

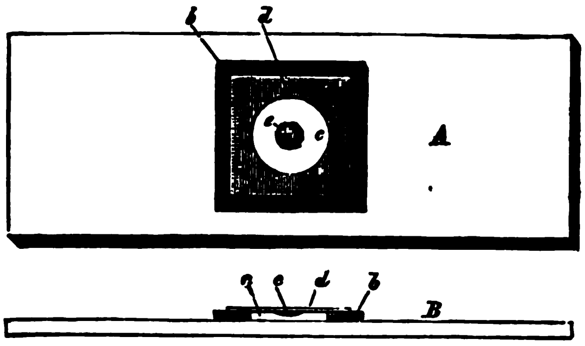

FIG. 5106.—Cell Slide showing Hanging Drop. *A*, Surface view; *B*, side view; *b*, edge of cell; *c*, hollow of cell; *d*, cover glass; *e*, hanging drop.

With a sterile scalpel an incision is made along the entire length of the body from the neck to the pubis. Lateral incisions are then made in the direction of each of the extremities, and the two large flaps thus resulting are turned back. The condition of the subcutaneous tissue, the presence of œdema, bloody effusions, enlarged lymphatic glands, etc., are noted. The glands or portions of the tissues may be transferred by means of sterile instruments to a sterile dish. Cover-glass smears or streaks can be made and examined either at once or later.

The abdominal and thoracic cavities are usually opened at the same time. The abdominal wall in the lower part of the body is slightly raised and nicked with sterile scissors; then the lower blade is inserted and the incision prolonged upward to the diaphragm. The ribs are then cut as low down as possible, and the wedge-shaped piece of the wall of the thorax is removed. The condition of both cavities and of the organs is carefully noted. Cover-glass streaks are made from the peritoneal surfaces and from the cut surfaces of the organs, and examined either at once or later. Any fluid which is present in the cavities may be transferred to sterile tubes by means of the pipette.

Cultures should always be made from an intact organ. For this purpose it is cut open with sterile scissors, and a piece of the pulp removed on a sterile wire, or by the aid of a Nuttall spear or spatula (Fig. 5088). The heart blood is usually given preference for culture purposes. The pericardium should be opened, after which the surface of the heart is seared with a hot iron. An incision is then made into the ventricle, from which the blood can be removed by the aid of a looped wire. The best way of removing the heart blood is by means of a sterile Pasteur bulb pipette. The end of this is broken, flamed, and when cool it is inserted into the heart, and by suction the blood is drawn up into the pipette. The contents of the tube can then be used to inoculate culture media or for making blood streaks.

After the autopsy the animal should be placed in a vessel and steamed or autoclaved, and eventually burned. The board should be washed with mercuric chloride, and all instruments and utensils should be sterilized by steaming. Throughout the autopsy care must be taken to prevent infection, either by scattering the material on the floor or by its being carried away by insects.

Examination of Bacteria.—In order to gain some definite information regarding the bacteria which develop on the nutrient media, or in the animal body, recourse must be had to the microscope. The organisms may be examined in the living condition or in stained preparations. The former procedure is resorted to so as to learn all that is possible regarding the living cell: its form, size, color, granulations if any, motion, grouping of the cells, presence of spores, etc. Such facts are ascertained by making a preparation in which the bacteria will continue to live for some time.

Living Bacteria.—1. The simplest procedure is to place a drop of the bacterial liquid on a slide, after which the cover-glass can be applied and the preparation examined under the microscope. This method is useful for rapid orientation, but it has certain drawbacks, chief among which is the fact that evaporation takes place along the edge of the glass, and as a result currents are established in the liquid. Such currents tend to interfere with the observation of any one organism or group of cells. Again, a preparation of this kind cannot be kept under observation for any length of time on account of the desiccation which soon takes place.

2. The examination in a hanging drop, as it is called, obviates the difficulties mentioned. A rather thick slide with a concave well is used (Fig. 5105). A ring of vaseline is spread around the edge of this well. A clean cover glass, about three-fourths of an inch in diameter, is placed on the table, and a drop of water is applied to the middle by means of a looped platinum wire. It is desirable that the drop should spread out flat, and if it does not it is because the cover glass is not clean. The drop of water is then inoculated with a little of the culture. Just enough material is added so that the liquid is slightly cloudy. The vaseline-ringed slide is then inverted and brought down upon the cover glass. The preparation is turned over, and, if need be, pressure applied to the border of the glass so as to have an air-tight hanging drop. Under these conditions evaporation does not take place, and consequently the specimen may be examined for hours, if necessary, without any interference by currents due to evaporation. As mentioned above, this method can be used for the cultivation of bacteria, and thus their growth and multiplication can be followed out. In that case it is necessary to use a flamed cover glass and a sterile liquid.

Instead of the concave slide a so-called well slide can be used (Fig. 5106). This is essentially a square bit of glass with a circular opening which is cemented to an ordinary glass slide, and the hanging drop is then made in the manner described.

One disadvantage in either method lies in the fact that the drop is more or less convex, and consequently when using higher powers it is difficult to examine the deeper portions. This difficulty can be overcome by employing the Ranvier slide, which has a circular trough, and the portion within the circle is ground down so that its level is about 0.1 mm. below that of the slide. When a drop of liquid is placed within the circle and covered with a cover glass, the liquid spreads out into a thin layer, every part of which can be examined under the microscope. A ring of vaseline is placed along the edge so as to prevent evaporation. By flaming the slide and cover slip and using sterile liquid the preparation can be observed for several days if need be. This method is especially to be recommended for studying trypanosomes, malaria parasites, etc.

Staining of Bacteria.—In order to obtain good stains it is necessary to have good clean cover glasses. The cover slips, as purchased in the market, are unfit for use until they have been cleaned. One method of doing this is to heat the slips in a beaker with concentrated sulphuric acid and potassium bichromate. The cover glasses are then washed in running water, after which they are kept in alcohol. Another procedure which gives very satisfactory results is to soak the cover glasses first in alcohol, after which they are wiped with soft, washed linen, placed in an Esmarch dish and heated in a dry-heat sterilizer at about 200° for an hour or two. This high heat completely destroys the organic matter that may be on the glasses. A cover glass is not clean if a small drop of water, when spread over the surface, does not remain even but gathers into droplets.

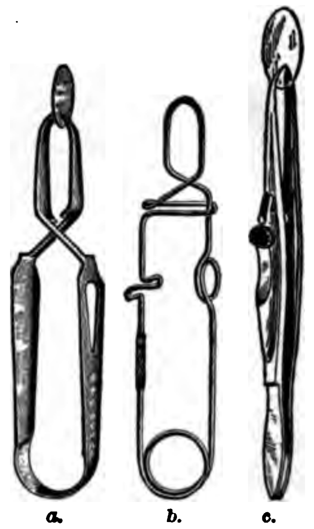

FIG. 5107.—Cover-glass Forceps. *a*, Cornet's; *b*, Stewart's; *c*, Novy's.

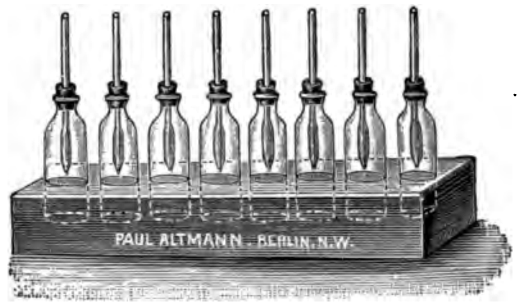
Several kinds of forceps have been devised for holding cover glasses while staining. The Cornet forceps (Fig. 5107, *a*) are well known, and are useful though rather awkward. Stewart's modification is widely used (Fig. 5107, *b*). A much more convenient forceps is shown in Fig. 5107, *c*. The lower blade has a thin edge which permits one to pick up the cover glass without contact with the fingers. The upper blade is bent in order to avoid capillarity, and is narrowed to a point so that the specimen is held by point contact. A catch serves to hold the cover slip in place.

Aniline Dyes.—The aniline dyes which are employed for staining purposes are either basic or acid in character. The former contain amido groups and are spoken of as nuclear stains, since they color the nuclei of cells as well as bacteria. The latter contain hydroxyl groups and do not stain bacteria, but are used chiefly for contrast coloring, and to some extent for decolorizing. The basic dyes are usually employed as salts of hydrochloric acid, while the acid dyes occur as sodium or potassium salts.

Among the basic aniline dyes which are commonly employed may be mentioned fuchsin, gentian violet, methyl violet, crystal violet, methylene blue, thionin, safranin, methyl green, neutral red, and vesuvin or Bismarck brown. These are all more or less crystalline powders, and while some are definite chemical compounds, others are mixtures. For this reason various brands are met with on the market, and it will be readily understood why the exact duplication of stains is not always possible.

It is advisable to keep on hand not only the solid dyes, but also stock solutions which are saturated alcoholic solutions The amount required to saturate will vary from two to five per cent.

The concentrated alcoholic solutions are never used as such, but serve for the preparation of the dilute dyes which are the stains proper. The latter are made by placing a few cubic centimetres of the concentrated dye in a small tincture bottle, and adding ten to twenty parts of water. This bottle is then provided with a cork and a piece of glass tubing which serves as a pipette. The different dilute dyes can be kept in a stand, such as is shown in Fig. 5108. The dilute dyes after a while undergo alteration and yield deposits. In that event they should be filtered before use, or else new dilutions should be made.



PAUL ALTMANN. BERLIN, N.W.

Fig. 5108.—Stand for Staining Solutions.

The acid aniline dyes are represented by eosin, acid fuchsin, and fluorescein. The concentrated and the dilute dyes are prepared as above.

The staining solutions may be used as such, or their properties may be accentuated by the addition of substances which act more or less directly as mordants. A number of these solutions are in daily use, and for that reason their preparation is here given.

Löffler's methylene blue is made by adding 30 c.c. of concentrated methylene blue to 100 c.c. of a 0.01-per-cent. solution of potassium hydrate. A similar solution with less alkali was first used by Koch. The alkali not only serves to make the cell more permeable, but also increases the staining power by liberating the free base from the dye.

Carbolic fuchsin, or Ziehl solution, is made by adding 1 gm. of fuchsin and 10 c.c. of alcohol to 100 c.c. of a five-per-cent. carbolic-acid solution. This stain is very widely used for simple as well as double staining. Czaplewski modified it by substituting glycerin for the alcohol. His solution is prepared by rubbing up in a mortar 1 gm. of fuchsin with 5 gm. of carbolic acid, and to this 150 gm. of glycerin and 100 c.c. of water are added.

Carbolic methylene blue, first employed by Kühne, consists of 1.5 gm. of methylene blue, 10 gm. of absolute alcohol, and 100 c.c. of a five-per-cent. solution of carbolic acid.

Carbolic theonin consists of 10 parts of a saturated solution of thionin and 100 parts of a one-per-cent. solution of carbolic acid (Nicolle).

Carbolic gentian violet is made the same as the preceding (Nicolle).

Aniline Water, Gentian Violet, etc.—The carbolic acid, like the alkali, favors the penetration of the stain. Aniline water acts in like manner and was first used by Ehrlich. To prepare the aniline water a few cubic centimetres of aniline are placed in a test tube, and this is then filled with distilled water and thoroughly shaken. The milky liquid is filtered through a moist filter. To the water-clear filtrate enough concentrated fuchsin or gentian violet is then added to make the liquid opaque, and so that it just begins to form on the surface a slight metallic film of precipitated dye. The solution is then used as such, but if the deposit is very marked it may be necessary first to filter it. The aniline water dyes do not keep very well, and for that reason it is well to make a fresh solution every time that it is to be used. Oil of cloves has been suggested by London as a substitute for aniline.

The aniline water stains were first employed by Ehrlich for coloring the tubercle bacillus, and are still used for that purpose. They are, however, employed especially for staining whips and in connection with Gram's stain. In the latter case, after the preparation has been stained with the solution, a mordant is applied, known as Lugol's solution, which serves to form a difficultly soluble compound between the dye and the cell contents.

Lugol's solution consists of 1 part of iodine, 2 parts of potassium iodide, and 300 parts of distilled water.

The Staining of Cover-glass Preparations.—These may be considered under the head of (1) simple, (2) double, and (3) special stains. For the simple stains, when it is desired to have a heavily colored preparation, either fuchsin or gentian violet is used. When it is desired to bring out structural characteristics, it is advisable to employ solutions which stain more feebly, such as methylene blue or thionin. In either case the simple or reinforced stains, given above, may be employed.

To make a stained preparation of a pure culture the procedure is as follows: A drop of water, preferably distilled, is placed upon a clean cover glass, which either lies on a board or is held in a pair of forceps. By means of a sterile platinum wire a minute amount of the bacterial growth is picked up and transferred to the water. Only enough should be added so as to impart to the water a slight cloudiness. The remainder on the wire is then burned off. The drop is then spread over the whole surface of the glass and allowed to dry in the air, or the process may be hastened by passing it above a flame. The air-dried preparation must now be fixed in order that the bacteria are not washed off in the subsequent treatment. The fixing is done by passing the cover glass three times through a flame. Care must be taken not to scorch the specimen, for in that case the dye will not act. It is well to turn down the flame so that it is at most but two inches high. The properly fixed cover glass is now covered with the stain, which is allowed to act for ten to twenty seconds. The dye is then washed off under the tap and the cover glass inverted upon a glass slide. Any water which may be on the surface of the slip should be removed by means of a piece of filter paper. The preparation can now be examined under a No. 7 objective, or with the one-twelfth inch oil immersion lens. If the specimen is such as to merit preservation a drop or two of water may be applied to the edge, and in this way the slip can be floated off without damaging the film. The excess of water can then be touched off with a piece of filter paper, after which the specimen is dried in the air or by passing it over the flame. The thoroughly dried film is then inverted upon a drop of Canada balsam placed on the centre of a clean slide. By gentle warming or by pressure the balsam can be made to spread out evenly.

Smear or streak preparations made from the fluids or organs of the body are stained in the same way. The fixation of the cover glass when it contains much proteid matter, as in the case of blood streaks, requires special care. The best results are obtained by immersing the slip for a few minutes in a mixture of equal parts of absolute alcohol and ether. Fixation is thus accomplished without any injury to the blood cells. It is sometimes advisable instead of adding the dye to the cover glass to float the latter upon the dye in a watch glass.

To make good blood preparations requires considerable care and experience. A small drop of blood is placed on a perfectly clean cover glass, which is held in a pair of forceps A second cover slip is then applied, evenly and without pressure, and as soon as the blood has spread out the two glasses are drawn apart. The blood cells must not be crushed and should lie in a single layer.

The smears from the cut surface of an organ are made by gently applying the cover glass, without pressure, and then drawing it away; or a piece of the organ may be taken up in the forceps and streaked over the cover glass, care being taken to leave only the thinnest film possible.

The ordinary glass slide is often used in place of the cover glass. The streaks or blood smears are made as in the case of the latter. When the growth is hard, as in the case of actinomyces, it is well to crush it between two glass slides.

Double Staining.—This procedure is resorted to when staining the tubercle bacillus and the allied acid-resisting bacilli. It is also used for staining spores, and in differentiating bacteria by means of Gram's stain. Other special methods are given under gonorrhœa and meningitis.

The group of acid-resisting bacilli, the type of which is the tubercle bacillus, are stained with more or less difficulty by the simple stains. The dye, however, can be forced into the cell by the aid of heat, and especially if the reinforced stains, such as carbolic fuchsin or aniline water gentian violet, are used. On subsequent treatment with acid and alcohol the ordinary bacteria, which chance to be present, are readily decolorized, whereas the acid-resisting retain the stain. A contrast color, such as methylene blue, will then stain the background and the ordinary bacteria a light blue.

Staining of the Tubercle Bacillus.—The cover glass is air-dried and fixed in the usual manner, after which any one of several methods may be used. The *Ziehl-Neelsen* method is usually employed. It is carried out as follows. The cover glass, held in the forceps, is covered with carbolic fuchsin and heated over the flame so that vapors are given off for one or two minutes. It is then rinsed in water and dipped for a few seconds in a twenty-per-cent. solution of nitric acid, after which it is washed in dilute alcohol (sixty per cent.) till it is almost colorless. Methylene blue is then applied for a few seconds and washed off. The specimen is transferred to a slide, the surface dried, and examined under the microscope. The tubercle bacilli will appear red on a blue background. The ordinary bacteria will appear blue.

The *Koch-Ehrlich method* consists in staining with aniline water fuchsin or gentian violet with the aid of heat for a few minutes. The specimen is then decolored in thirty-five-per-cent. nitric acid for about a quarter of a minute, washed in dilute alcohol till nearly colorless, after which methylene blue or Bismarck brown is applied for a contrast color.

In the *Fraenkel-Gabbet method* the preliminary staining is effected with carbolic fuchsin as above. The decoloration and contrasting is done at once by immersing the cover glass in a saturated solution of methylene blue in the following: Sulphuric acid 25 parts, alcohol 50 parts, distilled water 1,000 parts. It is then rinsed with water and examined.

Czaplewsky's method differs from the preceding in the way the decoloration is effected. He employed for this a solution of 1 gm. of fluorescein and 5 gm. of methylene blue in 100 c.c. of alcohol. The specimen is first stained with carbolic fuchsin; then, without rinsing in water, it is placed for a few seconds in the fluorescein methylene blue solution. Finally it is dipped ten or twelve times in a solution of 5 parts of methylene blue in 100 parts of alcohol. It is then washed with water and examined.

Numerous modifications of these methods have been proposed, but they possess no special advantage over those given.

Staining of Spores.—The cover-glass preparation is treated for some minutes with hot carbolic fuchsin, either on the forceps or by floating on the dye. It should then be rinsed and examined in water. If the spores are colored the next step is taken; if not, then the heating with the dye is continued until they are stained. The specimen is then decolored in dilute acid and alcohol until the spores stand out red on a colorless background. Methylene blue is then applied for a contrast, washed off, and the preparation is ready for examination. The bright red spores are seen within the light blue cells. This method requires considerable care, and every step must be controlled by frequent examinations under the microscope.

In order to enable the dye to more readily enter the spore, Möller treated the cover glass, first, for a minute or two with a five-per-cent. solution of chromic acid, after which essentially the above procedure was followed. By repeated passage through the flame or by heating with strong sulphuric acid for a few seconds the substance of the spore can be disintegrated so that on subsequent staining with carbolic fuchsin the spores will readily take the dye. This treatment, however, destroys the original cell, and hence contrast coloration is not possible.

The Gram Stain.—This is one of the most valuable methods in bacteriology, since it often serves to distinguish between organisms which otherwise resemble each other very closely. The cover-glass preparation is floated for a few minutes on aniline water gentian violet, or on carbolic gentian violet. Heat may be applied, but in that case the excessive staining will interfere with the subsequent decoloration. The specimen is then rinsed in water and immersed in Lugol's iodine solution for two or three minutes. After rinsing in water it is then placed for a few minutes in strong alcohol until most of the dye has been washed out. Very dilute eosin solution is now applied for about five seconds. After thorough washing with water it is ready for examination. The organism will appear a deep violet on a pink background.

Gram's method is applicable to the bacilli of anthrax, symptomatic anthrax, diphtheria, leprosy, malignant œdema, mouse septicæmia, rouget, tetanus, tuberculosis, the Fraenkel diplococcus, micrococcus tetragenus, the various staphylococci and streptococci, actinomyces, moulds, and yeasts. It is not given by the bacillus of glanders, typhoid fever, hog cholera, Asiatic cholera, chicken cholera, influenza, plague, Friedländer's bacillus, colon bacillus, gonococcus, rhinoscleroma, and recurrent fever spirillum.

The Staining of Flagella.—Special care must be given to the preparation of the cover glass. The cultures should be made on freshly inclined, moist agar, and should, as a rule, be less than twenty-four hours old. A very dilute suspension of the growth is made, and when spread over the cover glass is allowed to dry in the air. The fixation must be done with the least amount of heat possible. This can best be done by passing the cover glass, held between the thumb and forefinger, through the flame.

In Löffler's method the specimen is covered with a mordant solution which consists of 100 parts of a twenty-per-cent. tannic-acid solution, 50 parts of a cold saturated ferrous sulphate solution, and 10 parts of alcoholic fuchsin. The cover-glass is heated over the flame so that vapors are given off for a minute or two. Every trace of the mordant must then be removed by washing with water, and if it has dried down around the edge, it should be removed with a knife. The last traces of the mordant can be removed by momentary immersion in absolute alcohol. The specimen is then heated with aniline water fuchsin for a couple of minutes, washed with water, and examined. The chief difficulty in this method lies in the formation of a heavy deposit of foreign matter, which masks the bacteria.

Fischer's mordant is a slight modification of that of Löffler. It consists of 2 gm. of dry tannin, 20 c.c. of water, 4 c.c. of ferrous sulphate (1:2), and 1 c.c. of concentrated alcoholic fuchsin. The aniline water fuchsin is made by adding about 5 gm. of fuchsin, and 1 c.c. of a one-per-cent. solution of sodium hydrate to 100 c.c. of aniline water.

Bunge employed a mordant consisting of 75 parts of concentrated tannin solution, 25 parts of a five-per-cent. solution of ferric chloride, and 10 parts of a concentrated aqueous fuchsin solution. After standing some days hydrogen peroxide is added until a reddish-brown color is obtained.

Pitfield makes use of a single solution of mordant and dye. Two solutions are first prepared: (1) consisting of 1 c.c. of saturated alcoholic gentian violet and 10 c.c. of saturated aqueous alum; (2) consisting of 1 gm. of tannic acid and 10 c.c. of distilled water. The two solutions are filtered and then combined. The mixture is heated on the cover glass over a flame for about a minute, and then washed off.

Van Ermengem's method is essentially different. The cover glass is warmed for about five minutes with a fixing solution consisting of 60 c.c. of a twenty-per-cent. tannin solution, 30 c.c. of two-per cent. osmic-acid solution, and four to five drops of glacial acetic acid. It is then washed with water, rinsed in alcohol, and dipped for one or two seconds in a sensitizing solution of silver nitrate (one-half to one per cent.). After this it is placed for a few seconds in the reducing solution which consists of 5 parts of gallic acid, 3 parts of tannic acid, 10 parts of sodium acetate, and 350 parts of distilled water. It is again placed in the silver nitrate solution, in which it is moved about until the liquid darkens; after which the preparation is washed with water, dried, and examined.

Of the numerous other modifications which have been proposed that of Gemelli only need be given. Gemelli cleans the cover glasses in a boiling mixture of potassium bichromate (three per cent.), and sulphuric acid (five per cent.). After washing in water they are kept in alcohol. Before use each cover glass is flamed several times. Gelatin cultures developed at 37° C. are said to give the best result. A loopful is transferred to 5 c.c. of water in a watch glass, and from this suspension a drop is taken and spread over a cover glass, which is then set aside over calcium chloride to dry. The specimen is then placed for ten to twenty minutes in a one-fourth-per-cent. solution of potassium permanganate. The preparation is now washed well in distilled water, after which it is placed in a three-fourths-per-cent. solution of calcium chloride (?), to which has been added a one-per-cent. solution of Grübler's neutral red in the proportion of twenty to one. After remaining in this for fifteen to thirty minutes the specimen is washed, dried, and mounted. The method is said to give excellent and sure results without the annoying precipitates which form in the other procedures.

Staining of Capsules.—Welch's method consists in treating the cover glass with glacial acetic acid for a few seconds. The excess of acid is drained off with a filter paper, after which the specimen is washed in aniline water gentian violet, and finally in a sodium chloride solution (0.85 to 2 per cent.). The heavily stained bacillus will be found to be surrounded by a pale violet halo.

Nicolle treats the cover glass with a mixture of one per cent. carbolic acid (100 parts) and concentrated glacial alcoholic gentian violet (10 parts). It is then washed in absolute alcohol containing one-third its volume of acetone, rinsed in water, dried and mounted.

Staining of the Babes-Ernst Granules.—Neisser recommends the following method as a means of differentiating the diphtheria bacillus from like organisms. A culture grown on Löffler's serum should be used. The specimen is treated for one to three seconds, or a little longer, with the following solution: 1 gm. of methylene blue, 20 c.c. of absolute alcohol, 50 c.c. of glacial acetic acid made up to one litre with distilled water. It is then washed with water and stained with Bismarck brown (two per cent. aqueous solution) for three to five seconds. Finally it is washed with water and examined. The blue granules will stand out in the light brown bacilli.

Piorkowski heats the preparation for one-half to one minute with an alkaline solution of methylene blue, then decolors for five seconds in alcohol containing three per cent. of hydrochloric acid. A one-per-cent. aqueous eosin is applied for contrast, after which the preparation is washed and examined.

Romanowsky's Chromatin Stain.—This method is extremely valuable for staining protozoal parasites, such as those of malaria and the trypanosomes. When properly carried out it gives an admirable differentiation of the chromatin, which appears red on a blue background. Nocht's modification gives very good results, and is briefly as follows: A solution of one-per-cent. methylene blue and one-half per cent. of sodium carbonate is kept at about 60° C. for several days to "ripen." The change which takes place is one of slow oxidation, and as a result a number of products form, among which is the one which is essential to this method. This active red constituent has been designated as methylene azur. To about 2 c.c. of water in a watch glass two to three drops of a one-per-cent. solution of eosin are added, and then the altered blue, drop by drop, till the eosin tint just disappears. The specimen is floated on this dye for five to ten minutes, after which it is washed and examined.

Independently Wright, Leishman, and Reuter arrived at a simple modification. The ripened or polychrome methylene blue is treated with an eosin solution to slight excess. The precipitate, which Reuter has called a methylene-blue eosin, is then filtered, washed and dissolved in methyl alcohol. This solution can now be obtained from Grübler. Thirty drops of this are added to 20 c.c. of distilled water in a large watch glass or Petri dish. The specimen, which can be fixed with ether alcohol or with formaldehyde alcohol (10:90), is immersed in the dye for fifteen to thirty minutes. It is well gently to agitate the liquid from time to time. It is then washed, dried, and mounted.

Giemsa prepares the stain by adding 1 c.c. of a 0.08-per-cent. solution of methylene azur hydrochloride, Höchst, to 10 c.c. of a 0.005-per-cent. aqueous solution of Höchst eosin. Laveran employs 1 c.c. of a one-per-cent. solution of azur, 2 c.c. of a 0.1-per-cent. solution of eosin, and 8 c.c. of water. The specimen is stained for ten minutes, then washed and immersed for two to three minutes in a five per-cent. tannic solution, after which it is washed, dried, and mounted.

Impression Preparations of Colonies.—It is very often desirable to reproduce or preserve the characteristic surface colonies. The selection of the surface colony is made under the microscope, after which the tube of the instrument is raised and a cover glass is dropped down upon the colony. Gentle pressure is applied, the cover glass lifted off, air-dried, fixed, and stained with methylene blue in the usual way.

Staining of Sections.—In order to study the finer distribution of bacteria in the body of an infected animal it is necessary to harden portions of the different tissues and organs, which are then cut up into sections. The tissue may be cut by the aid of a freezing microtome, but the best results are obtained when the material is embedded in celloidin or in paraffin. The latter is especially to be recommended. The methods which are used for this work are essentially histological, and need not be considered in this connection.

To obtain a simple stain the section is placed in the dilute aniline dye for about five minutes. Dilute carbolic fuchsin or carbolic methylene blue are very good for this purpose. It is then washed thoroughly in water and transferred to very dilute acetic acid (1 c.c. of glacial acetic acid to 1,000 c.c. of water). The section is now placed in strong alcohol for one-half to one minute to remove the excess of dye. After washing in water it may be examined, and if the decoloration has not been sufficient, the treatment with alcohol can be repeated. When properly differentiated the section is placed for a few seconds in absolute alcohol for dehydration, then cleared in oil of cloves, passed through xylol and mounted in Canada balsam.

In Kühne's method the sections are stained in carbolic methylene blue and differentiated in one-half per cent. hydrochloric acid, rinsed in dilute lithium carbonate solution, then in water. The section is transferred to absolute alcohol, which is slightly colored with methylene blue for one-half minute; then for a few minutes to aniline oil containing methylene blue, finally into clear aniline oil, turpentine, xylol, and balsam.

Nicolle stains the sections in carbolic thionin, washes in water for about a minute, dehydrates with absolute alcohol, clears up in oil of cloves, and mounts in balsam. Another procedure employed by him is to stain first with Löffler's methylene blue, differentiate in one-half per cent. acetic acid, and fix in ten-per-cent. solution of tannin for a few seconds. The section is then washed, dehydrated, cleared, and mounted.

Gram's stain is applied to sections in the following manner: The section is placed in the freshly prepared aniline water gentian violet for about ten to fifteen minutes, after which it is washed in water, or better in aniline water, to remove the excess of dye. The section is then placed in Lugol's iodine for three to five minutes, transferred to absolute alcohol, in which it is tilted about until the excess of the stain has been removed and only a pale violet color remains. Ebner's solution may also be used for decoloring. It is counterstained in very dilute eosin for about a minute, washed in water, dehydrated in absolute alcohol, cleared in cloves, and mounted.

Bismarck brown may be used for a contrast color, or Weigert's picrocarmine. The latter may be made by adding 1 part each of carmine and ammonia to 50 parts of water; to this solution picric acid is added until a precipitate forms which is dissolved by the addition of a little ammonia; finally a few drops of carbolic acid are added.

Tubercle and leprosy bacilli can be stained in sections by applying the principle employed for cover-glass preparations. The carbolic fuchsin should be warmed to about 40° C. in a Petri dish. The sections remain in this solution for fifteen to thirty minutes, after which they are washed in water to remove the excess of dye. They are then decolored in dilute acid, or better in Ebner's solution. The latter consists of one-half part each of sodium chloride and hydrochloric acid, 80 parts of water, and 100 parts of alcohol. The faint pink sections are then placed in Löffler's methylene blue solution for about half a minute, after which they are dehydrated in absolute alcohol for a few seconds, transferred to xylol, and mounted in balsam.

DIAGNOSTIC METHODS.—The general principles which have been given find their practical application in the diagnosis of disease. It is desirable, therefore, to indicate briefly the way in which these methods are applied.

1. *Actinomycosis.*—The pus should be examined unstained under a cover glass for the characteristic yellowish, radiating masses with club-shaped threads along the border. Permanent preparations may be made by making smears, and staining either by the simple or by the Gram method. The pus may be hardened in mercuric chloride, sectioned and stained by Gram. Curettings may be treated in like manner.

2. *Anthrax.*—Cover-glass smears of the blood are stained by the simple and by the Gram method. Confirmation of the nature of the organism found can be obtained by inoculating a white mouse or a guinea-pig subcutaneously with the material. This with the cultural characteristics will enable identification.

3. *Bubonic Plague.*—This diagnosis may be made during life, but more often after death. In the pneumonic form the blood-streaked sputum can be used for simple stains, which will show large numbers of the small rods. In the bubonic type the enlarged gland may be punctured and thus material obtained for examination. The detection of the bacillus in the blood can be effected by drawing several cubic centimetres of the blood from a vein by means of a syringe. Agar plates, one part of blood to two parts of agar, should then be made. Whether the result is apparently positive or wholly negative, an animal experiment must be carried out. The suspected material is inoculated subcutaneously into a guinea-pig, and if plague bacilli are present, death will ensue in from five to eight days. Cultures and smears from the animal will then establish the nature of the organism. An important cultural characteristic is brought out by planting the material on agar containing about three per cent. of salt. Round or pear-shaped involution forms develop. The smears from the body should be stained with Löffler's methylene blue or with carbolic thionin. The short rods take the bipolar stain, and if the material is old, roundish involution forms or "doughnuts" will be met with. The bacilli are not stained by Gram.

4. *Cholera.*—The examination may aim to find the cholera vibrio in the drinking-water, or it may be concerned with the diagnosis of the disease. In the latter case the rice-water discharges should be collected and searched for mucous flakes. Preparations from these, when stained, will show the presence of the characteristic vibrio. The appearance of the colonies on gelatin and on agar plates, the growth in bouillon, and the indol reaction serve to identify the organism. The intraperitoneal injection of the culture into a guinea-pig should also be practised. The most important reaction is that of Pfeiffer. It consists in injecting into the peritoneal cavity of a guinea-pig a mixture of the cholera antiserum and the suspected organism. Every few minutes a drop of fluid is withdrawn from the peritoneal cavity by means of a capillary tube and examined. If the organisms persist, it is safe to say that they are not those of true cholera. The latter under these conditions lose motion, become granular, and soon disappear.

It may be possible under exceptional circumstances to detect the cholera vibrio in drinking-water by ordinary plating on gelatin. Obviously the number of the organisms may be so small and the other bacteria may be so numerous that it is impossible to obtain positive results by this method. To overcome this difficulty Schottelius devised his enriching method. This consists in adding the suspected water to a one-per-cent. solution of peptone and incubating at 37° C. for about twelve hours. The actively motile cholera spirilla, on account of their need of oxygen, accumulate as a cloudy layer near the surface. A loop of this liquid is then transferred to and spread over the surface of gelatin and agar plates, and the further identification is then easily effected. Obviously the peptone may be added direct to the water, for example 100 c.c., and in this way the presence of a very few vibrios in a large volume of water may be detected.

5. *Diphtheria.*—The necessary material for the examination is obtained either by means of a Roux spatula (Fig. 5083), or by a cotton swab. The cotton swab is usually employed, and is made by twisting a piece of cotton about the end of a thick iron wire. The wire should be about six inches long. The cotton end is then placed in a plugged test tube which is sterilized by dry heat. Whether a pseudo-membrane is present or not, scrapings are made from the surface of the affected tonsils or throat and examined. Usually the swab is streaked over the surface of one or more tubes of plain, or better Löffler's serum. These tubes are incubated overnight and examined in the morning for the characteristic diphtheria bacilli. The cover-glass preparations made from these cultures are stained with Löffler's methylene blue. The swollen rods with irregularly stained contents are easily identified. In case there is any doubt as to the diagnosis, it is advisable to inoculate a guinea-pig with the culture material.

Whenever possible it is advisable to make cover-glass preparations direct from the false membrane. These are then stained with Löffler's methylene blue. The diagnosis can be made thus often in a few minutes.

6. *Dysentery.*—It is necessary to distinguish between two types, the bacillary and the amœbic. The examination for amœbæ should be made at once, immediately after the stool is passed, in order to obtain actively motile organisms. A drop of the thin fæces or suspension is placed on a slide, covered with a cover glass, and examined under the microscope. The characteristic motion will leave no doubt as to the nature of the organism. The motion can be observed best on a warm side or in an incubator. Staining is not necessary.

The bacillary form is due to the bacillus dysenteriæ, and the diagnosis of this type necessitates the detection of this organism. Agar plates should be made from the stools and developed at 37° C. From the suspected colonies subcultures should be made to glucose agar, lactose litmus agar, and mannite litmus agar. The pure cultures should finally be tested for agglutination with the serum of a dysenteric patient. Too much care, however, cannot be exercised in drawing conclusions based upon a positive agglutination reaction, since this test is undoubtedly given by allied organisms.

7. *Gonorrhœa.*—Cover-glass preparations made from the pus will serve to establish the diagnosis in nearly all instances. They should be stained with Löffler's methylene blue. A fair double stain can be obtained by first applying eosin, after which the blue can be used for a few seconds. The result is a more or less pink background with blue gonococci. Gram's method is negative.

Von Wahl recommends the following method of double staining which brings out the gonococci as reddish-violet to black cells on a light green background. The stain consists of: Concentrated alcoholic solution of auramin, 2 c.c.; ninety-five-per-cent. alcohol, 1.5 c.c.; concentrated alcoholic solution of thionin, 2 c.c.; concentrated aqueous methyl green, 8 c.c.; water, 6 c.c. The auramin and thionin solutions are prepared by dissolving the dyes in hot ninety-five-per-cent. alcohol to saturation, cooling, and filtering. The cover glasses are stained for five to fifteen seconds. The ordinary bacteria stain feebly or not at all.

The detection of the gonococcus in septicæmic cases can be accomplished by drawing 5-10 c.c. of blood from the vein of the arm and adding this, in about equal parts, to melted agar at 45°. The mixture is at once poured into Petri dishes, and these are developed at 37° C. In this way the gonococcus can be detected when direct stains would fail to show the organism.

The culture test for the gonococcus is rarely resorted to on account of the difficulty of obtaining the necessary blood or serous fluids. The ordinary media have always been regarded as unfavorable for the growth of this organism. According to Thalmann, Wildbolz, and others, the gonococcus can be grown on ordinary one-and-one-half-per-cent. meat peptone agar. Thalmann recommends very highly such a medium for diagnostic purposes, and especially where direct microscopic examination is unsatisfactory or negative. The acidity of ordinary agar or bouillon is reduced by the addition of two-thirds of the amount of alkali necessary to make the media neutral to phenolphthalein. The preparation of these media has been given.

8. *Leprosy.*—The leprous nodules are characterized by the presence of enormous numbers of the specific bacillus which can be readily detected by staining. The Ziehl-Neelsen method, as employed for the tubercle bacillus, will give excellent results if the tissue is reasonably fresh. When kept for some time in alcohol the bacilli lose their staining properties so far as this method is concerned, but they can still be found by means of Gram's method. Animal inoculations and cultures are not possible.

9. *Meningitis, Cerebro-spinal.*—The diplococcus intracellularis meningitidis is found in the cerebro-spinal fluid. Hence during life it is necessary to remove some of the fluid by lumbar puncture. This fluid should be planted abundantly on glycerin, or better on serum agar. Cover-glass preparations made direct will show the typical organism resembling the gonococcus in form and in its presence within the leucocytes. It is not stained by Gram's method, but can be given a double stain by that of Pick and Jacobsohn, or by the modification suggested by Fraenkel. The dye is made by adding to 20 c.c. of water eight drops of a saturated solution of methylene blue, and then forty to fifty drops of carbolic fuchsin. The dye is allowed to act for five minutes. The cocci are blue on a red background.

10. *Pneumonia.*—In all pneumonic conditions the blood-streaked sputum should be examined by making simple and Gram stains. In this way it becomes possible to recognize the pneumonic form of plague. Ordinarily, however, pneumonia is due to the Fraenkel diplococcus and at times to the Friedländer pneumobacillus. The form, staining and cultural properties of these organisms permit ready differentiation and identification. The lance-shaped diplococcus of Fraenkel, as found in the body, is surrounded by a capsule, and is stained by Gram's method. The colonies and cultures on glycerin agar are very faint and dewdrop-like, and tend to die out in a few days. Their vitality and virulence are best preserved by cultivating them on rabbit blood or serum agar. In doubtful cases the material should be injected under the skin of the ear of a rabbit. If death results the diplococcus will be found in large numbers in the heart blood and organs of the animal.

11. *Rabies.*—The cause of this disease is as yet unknown, but it is to be found, in pure condition so to speak, in the brain and spinal cord of the affected person or animal. The diagnosis rests upon animal inoculation with such material. A few drops of a suspension of the brain or cord are injected subdurally into a rabbit or guinea-pig. The method has been already described.

The histological changes in the nervous system are very slight, and it has been suggested that the diagnosis of rabies may be hastened by making an examination of sections of the cord and ganglia. The lesions are not sufficiently marked in all cases to permit diagnosis, and for that reason this method should not be relied upon to the exclusion of the only positive test, that of animal inoculation.

12. *Tetanus.*—The point of inoculation must be found first. This may not always be easy, for the original wound may have healed over. The portal of entry may be a bad tooth, or the wound produced by an old rusty nail, a splinter of wood, or the powder grains of a pistol. Cover-glass preparations should be made from the pus, if there is any; and, if not, from such serum, blood or tissue as can be obtained from the wound. They should be stained with carbolic fuchsin. The specimen should be examined for "drum sticks" or rods with terminal spores, and particularly for the presence of rather narrow, long bacilli. These are present even when no spores can be found.

Cultures should be made on glucose litmus gelatin, and at the same time a series of glucose agar plates should be made and developed at 37° C., either in hydrogen or in the pyrogallate apparatus. The original tissue should be planted under the skin of a white mouse and of a guinea-pig. The cultures when developed are carefully searched for the drum-stick forms.

13. *Tuberculosis.*—The pulmonary form is usually recognized by an examination of the sputum, preferably that which has been collected in the morning on rising. The cheesy particles, if such can be recognized, should be picked out by means of the wire and spread over the cover glass. The specimen is then stained by the Ziehl-Neelsen method already given. The red rods on a blue background are readily recognized.

The same method is employed in the examination of pleuritic fluid, pus, urine, milk, etc. In all these examinations, however, two facts should be borne in mind. In the first place the tubercle bacilli may be present, but in such small numbers that they escape detection. Again, acid-resisting organisms, such as the leprosy, smegma, timothy grass bacillus, etc., may be present, and may be easily mistaken for the tubercle bacillus.

In either case it is the animal experiment which will serve to remove the doubt. When the tubercle bacilli are few or doubtful, it is well to submit the material to preliminary centrifugation. The deposit can be used then for staining and for injection. The injections should be made into the peritoneal cavity of the guinea-pig. If tubercle bacilli are present in the material used, even if so scarce as to be unrecognized by the microscope, the animal will develop the disease and will die in the course of a month or two. The tuberculous organs and glands can be examined then for tubercle bacilli, and cultures can be made on glycerin agar, potatoes, and on Hesse's Heyden agar. The acid-resisting bacilli, other than the tubercle bacillus, are not fatal to animals, and, moreover, the histological changes which they induce are quite different from those caused by the tubercle bacillus.

14. *Typhoid Fever.*—The verification of the diagnosis is usually made by means of the agglutination test of Widal, which will be described later. The direct detection of the typhoid bacillus in fæces, urine, blood, rose spots, and in water presents marked difficulties. The

reason for this lies in the very great similarity which exists between the typhoid and the colon bacillus. Numerous methods have been devised for the purpose of effecting a distinction between these two organisms; and while it is an easy matter to differentiate between the pure cultures of the typical organisms it becomes vastly more difficult under natural conditions, especially when, as often is the case, the para-colon and para-typhoid bacilli are present.

Some of these methods endeavor to restrict the growth of the colon and of adventitious bacteria by the addition of antiseptic substances to the media. Thus carbolic bouillon, Parietti's carbolic hydrochloric-acid broth, and crystal violet are used with this object in view, but there can be no doubt that weak typhoid bacilli are also inhibited.

Other methods are based upon the unequal diffusion of the two organisms in special media. The Stoddart, Hiss, and Capaldi media belong to this class.

Again, the effort is made to bring out differences between the colonies of the Eberth and colon bacilli, as in the case of the Holz potato gelatin, Elsner, Weil, Hiss, and Piorkowski media. These are all described in the foregoing pages. Still other methods seek to utilize the differences in the fermentative powers of these organisms, as evidenced in the production of gas, acid products, etc. Lastly, there are several methods which have only recently been devised in which the distinction is effected by means of the agglutination reaction. That of Windelbandt, as modified by Schepilewsky, certainly seems to be effective in detecting typhoid bacilli in tap water. Its real value in the examination of typhoid fæces remains to be demonstrated.

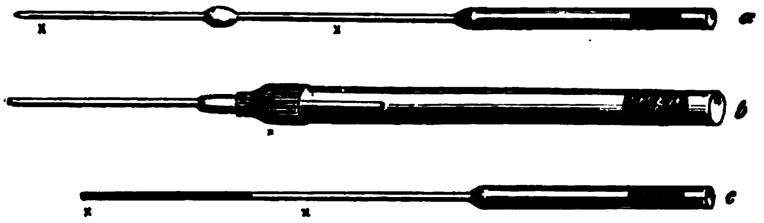


FIG. 5109.—Filling of Capillary Tubes for Thermal Death-point Determinations. c, Tube filled ready to be sealed at x; b, emptying of tube. (Novy.)

Schepilewsky's procedure is as follows: Several cubic centimetres of the infected water are added to 50 c.c. of bouillon in an Erlenmeyer flask, which is then incubated for twenty-four hours at 37° C. The culture is now filtered through a sterile cotton filter in order to remove any compact masses of bacteria which may be present. The filtrate is received in conical centrifugating tubes. A very active serum from a rabbit, which has been immunized to the typhoid bacillus, is then added to the cloudy filtrate, and this is set aside for two to three hours at 37° C. If many typhoid bacilli are present, visible agglutination may be noted; but if they are not abundant, the masses will be so small that agglutination may not be detected. In either case the tubes are centrifugated for one to two minutes, after which the fluid is decanted and the tubes are inverted so as to drain as completely as posssible. Sterile sodium chloride solution is then added to the tubes and the deposit is taken up and transferred to a sterile test tube which contains glass beads. By vigorous shaking the agglutinated masses can now be broken up and homogeneous suspension obtained. A glass rod, bent at right angles, is then dipped in the suspension, and streaked thoroughly over the surfaces of a number of plates of the special agar. The latter is a three-per-cent. agar, to which after sterilization in an autoclave a lactose and lacmoid solution is added. This consists of 1.5 per cent. lactose and 0.04 per cent. lacmoid, and before addition is boiled fifteen minutes. The Petri dishes are developed at 37° C. for twenty-four hours. The typhoid colonies are round, or oval, and sharp bordered; later they show the typical spreading form, and the color of the centre changes to a dirty yellow.

The typhoid-like colonies should then be examined under the microscope and submitted to further identification. A suspension of the colony may be tested for the agglutination reaction with typhoid serum. Pfeiffer's reaction may be tested for by injecting a mixture of antityphoid serum and the organism into the peritoneal cavity of a guinea-pig, as described under Cholera. The cultures should also be tested for gas production, indol, milk coagulation, and on the special plating media.

In the absence of the serum necessary for the above method recourse may be had to the plating medium of Hiss, the urine gelatin of Piorkowski, and the Drigalski-Conradi agar, the preparation of which has been given.

15. A number of infections due to moulds and allied forms and also to yeast-like bodies have been described. The former are represented by the streptothrices, or, more correctly, by the actinomyces of Madura foot and of cattle farcy. The yeast or blastomycotic affections have been noted in certain forms of dermatitis, and may even be systemic in character. In all these diseases the examination of the pus and of sections of tissue, as well as the culture of the organism, must be carried out.

16. *Protozoal Diseases.*—Several very important diseases are due to organisms of this class. The examination for amœbæ in tropical dysentery has already been touched upon. The sporozoa include among others the plasmodium of malaria, the piroplasma of Texas fever, of "spotted fever," and of horses, sheep, and dogs. The flagellata cause the various trypanosomatic diseases, such as the surra of Asia and of the Philippine Islands, nagana or the tsetse-fly disease of South Africa, dourine or "maladie du coït" of the Mediterranean littoral, caderas of South America, the gambian fever and the sleeping-sickness, the last two being diseases of man. Moreover, many animals harbor in the blood parasites of this group, as in the case of the wild rat.

In all suspicious cases the blood should be examined for these two groups of organisms. The plasmodium of malaria is found especially within the blood cells. The trypanosomes are free in the plasma. The blood may be examined direct under the cover glass, or in hanging drop, or in a Ranvier slide. Stained preparations can be made with methylene blue, thionin, or best with some modification of the Romanowski method. The preparation of the specimens and the staining methods have already been described. The trypanosomes of the rat and of nagana, cultivated by Novy and McNeal, are the only pathogenic protozoa which it has been possible to grow artificially. Their presence is best detected by direct examination of the blood, though at times they may be very difficult to find, and may require daily examinations for several weeks.

DETERMINATION OF THE THERMAL DEATH POINT OF BACTERIA.—In this work and also in testing disinfectants it is necessary to have almost homogeneous suspensions of the organism to be tested. Water suspensions should be used first, and later those of bouillon, serum, etc. The liquid is introduced by means of a bulb pipette into the tube of an agar culture. The growth is rubbed up as much as possible, and the suspension is then transferred to a sterile glass-wool filter. In this way the masses of bacteria are removed. The cloudy filtrate may be used as such, or it may be diluted so as to have fewer organisms in the test. It may be used as such for determining the action of moist heat and for testing disinfectants. Again, for dry-heat work and for many disinfecting tests the suspension is allowed to dry upon the surface of sterile glass slips, glass or garnet beads, silk threads, muslin squares, etc.

To test the action of dry heat a number of cover glasses on which the test organism has been dried are placed in a sterile Petri dish and exposed to a given temperature.

At given intervals a specimen is removed and planted in bouillon.

To test the action of moist heat the best procedure is to draw up the liquid into sterile capillaries, as shown in Fig. 5109. The tube is sealed, below and above, the liquid. The advantage of this method lies in the fact that the heat promptly penetrates every part of the suspension. A number of tubes thus equipped are placed in a water-bath, the temperature of which is kept at a constant point by means of a regulator. At intervals a capillary is removed, cooled, opened at one end, and the contents are expelled into a tube of bouillon by gently touching the closed end to a flame.

Testing of Chemicals.—In this work it is necessary to distinguish between the antiseptic and the disinfecting action of a substance. The former refers to the amount of the substance which will inhibit the growth, but not necessarily kill the organisms. The latter implies the actual destruction of the test object. Obviously a substance which will kill bacteria, when diluted sufficiently will merely restrict their growth; and when the dilution is excessive will have no action whatever.

The antiseptic action is determined by adding to the suspension in bouillon varying amounts of the chemical so as to make different dilutions, for example: 1 in 500, 1 in 1,000, 1 in 5,000, 1 in 10,000, etc., solutions. The tubes thus equipped are then placed in the incubator for several days. The very weak solutions will show growths, while the very concentrated ones will show none. The amount which just inhibits the growth represents the antiseptic power of the substance.

The germicidal action of a gas, such as formaldehyde, is determined by exposing cover-glass preparations, silk threads, bit of muslin, etc., impregnated with the suspension, dry and moist, to the action of the gas in a tight room. At the end of the exposure the preparations are transferred to sterile tubes of bouillon and incubated.

The germicidal action of liquids is ascertained, either by adding the solution to the bacterial suspension or by immersing in the solution the dried cover-slip preparations mentioned. In the former case, at stated intervals, a small loop of the liquid is transferred to bouillon, while in the latter case the slip or thread is first rinsed in sterile water and then placed in the bouillon.

The Serum Agglutination Test.—The serum of an animal which has been immunized to a germ when brought into contact with a suspension of that germ will cause the organisms to gather in masses. This fact is utilized in the Widal test for typhoid fever. A drop of the serum from a typhoid patient is diluted with ten, twenty, thirty, fifty, one hundred drops respectively of water in a watch glass. A drop of each mixture is then transferred to a cover glass and inoculated with a very small amount of a fresh agar culture of the typhoid bacillus, care being taken to avoid an excess of the organisms. Hanging drops are then made and the preparations examined under the microscope. The limit of the reaction is indicated by the dilution which is just able to cause paralysis of motion and clumping in one hour. Instead of diluting with water some prefer to use a very young bouillon culture. The agglutination test is most delicate when carried out under the microscope. Very good results, visible to the unaided eye, may be obtained by adding the serum to bouillon cultures of the organism. The tubes thus treated should be set aside for some hours at 37° C. when the agglutinated masses will settle to the bottom and leave the liquid clear. When applying the test to a suspected case of typhoid fever it is not always possible to obtain large amounts of the serum. In such instances the blood may be placed in single drops on a sheet of filter paper, or better tinfoil. The dilutions can then be made with these drops of dried blood as with the serum itself. The application of this test to the recognition to the typhoid bacillus in drinking-water, fæces, etc., has been given.

Testing the Strength of Antitoxin.—The strength of an antitoxin is expressed in immunity units. A unit represents that amount of serum which will be just sufficient to save a 250-gm. guinea-pig against 100 minimum fatal doses of the diphtheria toxin. Thus if 0.1 c.c. of serum protects against this dose of poison, then it will contain 1 immunity unit, and 1 c.c. of such serum will contain 10 immunity units. It is possible to prepare diphtheria antitoxin of such strength that 1 c.c. will contain more than 1,000 immunity units. Usually, however, the serum as marketed contains about 200 immunity units per cubic centimetre.

The first essential is to ascertain the minimum fatal dose of the toxin, by which is meant the amount of toxin which will kill a 250-gm. guinea-pig on the fourth, or at most on the fifth day. The toxin itself is a bouillon culture of the diphtheria bacillus, which has been rendered sterile by the addition of a small amount of carbolic acid. The diphtheria culture should not be more than a week old.

Varying amounts of the serum are then added to portions of the toxin representing one hundred minimum fatal doses. These mixtures are then injected into guinea-pigs of the weight given. That fraction of a cubic centimetre of the serum which just suffices to save a guinea-pig under these conditions represents, as stated above, one immunity unit. The test is usually made with only ten minimum fatal doses, in which case the proper correction is made.

This method is subject to some error, inasmuch as it has been found that a serum which has been tested against one toxin will show a different value when tested against another. This is due to the fact that the toxin undergoes changes on keeping, and is converted into a non-poisonous body or toxoid, which, however, retains the power of combining with the antitoxin. For this reason Ehrlich proposed a new method of testing the antitoxic value of a serum. A standard dried antitoxin is made the basis of the measurement. This is diluted so that a given amount just represents one immunity unit. The test dose of toxin is then ascertained and represents the amount of toxin, which mixed with one immunity unit of serum, will cause death on about the fourth day. The serum to be tested is then diluted, mixed with the test dose of the toxin, and injected into guinea-pigs. If the animal dies in a day or two it is evident that the serum contains less than one immunity unit. If, on the other hand, it lives for seven or eight days, or even recovers, it shows that the amount of serum taken contains more than one unit. By using suitable dilutions of the serum eventually the point will be reached where the amount taken will represent exactly one unit.

Methods of Immunization.—Only the general principles of active immunization can be considered. The injections are made subcutaneously, intraperitoneally, and intravenously. When a soluble poison is injected, a true antitoxin develops in the animal and is present in the blood, and hence in the serum. This is the case in diphtheria, tetanus, and venom immunity. On the other hand, when the solid cell is injected, the serum may acquire anti-infectious properties, the best instance of which is seen in the anti-pest serum. The organisms may be killed by exposing them to the action of ether, chloroform, or to that of moist heat at 60° C. In special cases the attenuated living germ is used, and at times even the most virulent form is employed. By the injection of cells other than bacteria, diverse cytolytic sera are obtained. Thus the injection of the red blood cells gives rise to a hæmolytic serum. The temperature and the weight of the animal must be taken daily, since they afford the best indication of the condition of the animal.

Examination of Air.—The bacteria which chance to be present in the air are in a dried condition, and tend to settle when the motion of the air is lessened. The simplest method consists in exposing a plate of gelatin or agar to the air for a given length of time. Some of the organisms settle on the gelatin, and eventually give rise to colonies. Koch improved slightly upon this by placing the gelatin plate in the bottom of a sterile cylinder of known volume. After opening the cylinder in a given locality it is closed with a cotton plug and set aside, when the organisms contained in that volume of confined air settle to the bottom on the surface of the plate. The results, it will be seen, are crudely quantitative (Fig. 5110).

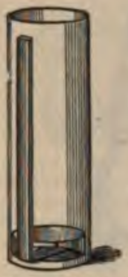

FIG. 5110.—Koch's Cylinder for Air Analysis.

Hesse's method consists in drawing the air through a large Esmarch roll tube (Fig. 5111). The volume of the air drawn through can be determined from that of the aspirating bottles. The bacteria in the air impinge upon the gelatin surface where they develop into colonies which can be counted and studied.

The apparatus of Petri, although very expensive, may be said to give the best results. It consists in the first place of an air pump, which automatically registers the movement of the piston, and thus gives the volume of the air which has been drawn through. The air is aspirated through a tube (Fig. 5112) containing several layers of sterile sand. The suspended bacteria are thus held back. At the close of the operation the sand is transferred to a Petri plate, where the bacteria will form colonies and thus become accessible for study.

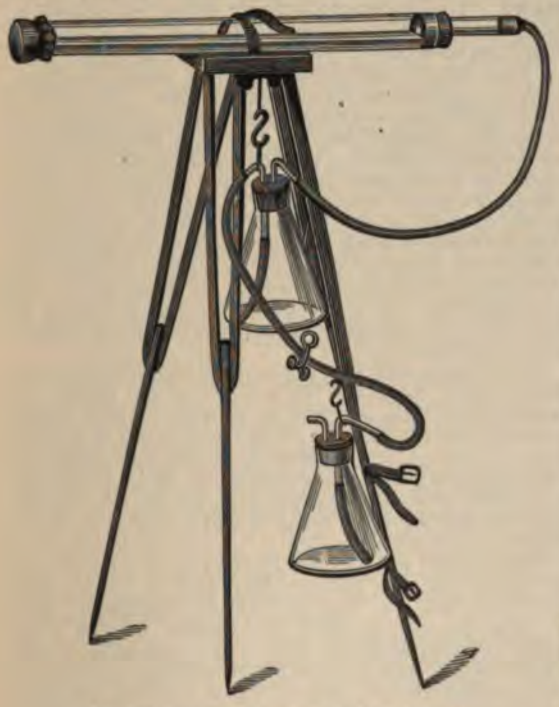

FIG. 5111.—Hesse's Apparatus for Air Analysis.

Instead of sand, Sedgwick and Tucker employed a filter of sugar. The special tube employed by them is shown in Fig. 5113. After the air has been drawn through, the sugar is tapped down into the wide portion of the tube, then gelatin is added and warmed until the sugar dissolves, after which an Esmarch roll culture is made in the same tube.

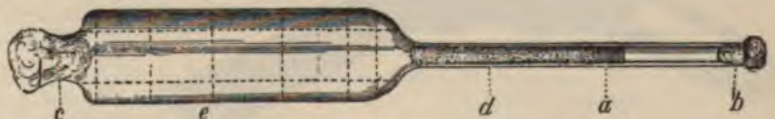

FIG. 5113.—Sedgwick and Tucker's Aërobioscope.

Other workers have filtered the air through liquid media or through gelatin. The most convenient form of apparatus of this kind is that of Wurtz, shown in Fig. 5114. A suitable amount of gelatin is placed in the sterile tube, then a known volume of air is drawn through, after which the gelatin is solidified over the inner wall of the tube, thus forming a roll culture.

Examination of Soil.—By means of a small sterile platinum spoon a definite volume of the soil may be transferred to a Petri plate, where it is thoroughly mixed with the medium. The colonies which develop can then be examined. In this way it is possible at times to demonstrate the presence of the anthrax bacillus in the soil of an infected locality. The detection of other pathogenic bacteria, as for instance those of tetanus and malignant œdema, can best be made by introducing a quantity of the soil under the skin of a guinea-pig or rabbit.

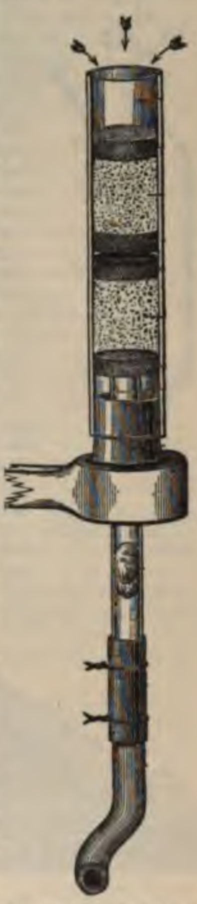

FIG. 5112.—Petri's Sand Filter for Air Analysis.

Examination of Water.—This is a very important procedure, and an enormous amount of work has been done to perfect the methods of work. The method followed will necessarily depend upon the immediate object in view. Thus the detection of the cholera vibrio is carried out in a different way from that used for the colon bacillus. The isolation of the cholera and typhoid organisms from water has already been described.

The water which is to be tested bacteriologically must be received into a sterile glass-stoppered bottle, and should be examined at once. The first step in the examination is to make gelatin plates. By means of a sterile pipette 1 c.c. of water is added to a tube of gelatin, mixed thoroughly, and the gelatin is then poured out into a Petri plate. In the same way plates are made with 0.5 c.c. and with one drop of the water. The gelatin plates are developed at 20° C. for several days. The colonies are then counted and examined in the usual way. When only a few colonies are present on a plate they can be readily counted with the eye. When the number is large special counters are made use of. That of Wolffhügel (Fig. 5115) is ruled in squares of 1 cm. and fractions thereof. Another form is that of Lafar. A very useful and cheap substitute is made by printing the divided circle on card paper. To make a count, the number of colonies in ten or more squares are ascertained and the average per square centimetre is obtained. The area of the gelatin on the plate is taken and then the total number of colonies on the plate determined, and the result is expressed per cubic centimetre of water.

Instead of using Petri plates, the Esmarch roll tube can be made. To count the colonies in such a tube Esmarch devised the counter shown in Fig. 5116.

When the number of colonies is likely to be extremely numerous, as in the examination of polluted water, it is advisable to dilute a portion of the sample with a known volume of sterile water. If the colonies are very numerous on a plate the counting can be carried out best under a microscope. Ehrlich stops are placed in the eyepiece or the special Ehrlich ocular may be used. The size of the opening in the ocular must be determined by means of a stage micrometer. The average number of colonies for a given sized opening is determined, and from this the total number on the plate is calculated.

The above method of examination gives approximately the number of bacteria which are present in a water, and to some extent information as to the kind of bacteria. It is of great value, therefore, in controlling the work done by the water filters. In order to ascertain the presence of pathogenic and other bacteria special methods must be resorted to. The method which has been employed during the past fifteen years in the Hygienic Laboratory of the University of Michigan consists in planting a cubic centimetre and a drop of the water in tubes of bouillon, which are then incubated at 39° C. If no growth forms, as often is the case, pathogenic bacteria may be said to be excluded. When a growth does form, a portion (1 c.c.) is injected into a guinea-pig. In case the animal dies the heart blood is examined for the kind of organism present. If no ill effects follow the injection, the water may be said to be free from pathogenic bacteria.

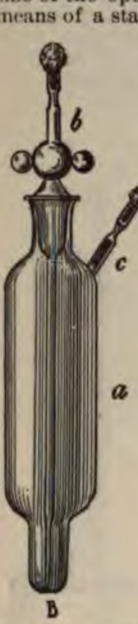

FIG. 5114.—Wurtz's Apparatus for Air Analysis.

Sewage contamination is usually indicated by the presence of colon bacilli and of streptococci. The presence of the former is tested for by means of the Smith fermentation tube (Fig. 5117); 1 c.c. of the water is added to glucose bouillon in the fermentation tube, which is then set aside at 37° C. The formation of gas indicates the probable presence of the colon bacillus, while the nonproduction of gas points to the absence of this organism. Further tests are necessary for identification.

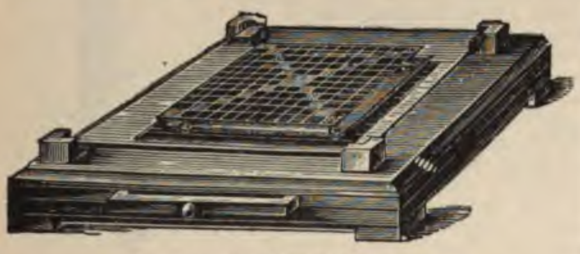

FIG. 5115.—Wolffhügel's Colony Counter.

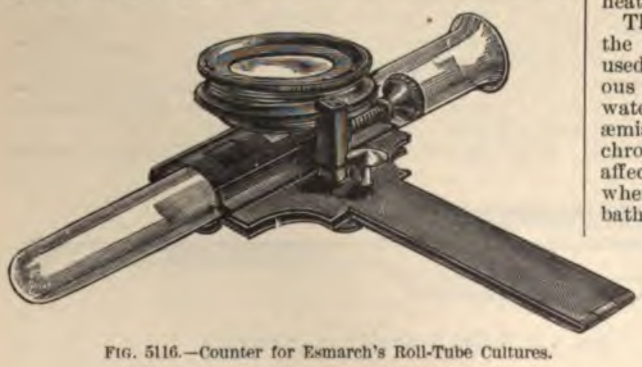

FIG. 5116.—Counter for Esmarch's Roll-Tube Cultures.

Litmus lactose agar plates should be made directly from the water and also from the fermentation tube when gas production is present. The formation of red colonies is indicative of the colon bacillus, since this organism ferments lactose, whereas typhoid-like bacteria do not. For the same purpose lactose bouillon is sometimes employed in the fermentation tube.

Another procedure is to plant the water in carbolic bouillon, or in Parietti's solution, in order to eliminate many of the more common bacteria.

Neutral red bouillon and agar is also used for cultivating the suspected colon bacillus. The water may be planted direct, or the red colonies which form on the plate may be used for inoculation. The coagulation of milk and the production of the indol reaction are additional tests of identification.

BADEN-BADEN AND THE BLACK FOREST, GERMANY.—The region of the Black Forest (Schwarzwald) lying to the east of the Rhine, between Karlsruhe and Basel (Switzerland), is a thickly wooded mountain range of great beauty and picturesqueness, containing many climatic and mineral-water health resorts. The most of these resorts have only a summer season extending from about the middle of May to the end of September; but the open-air cures for pulmonary tuberculosis remain open the whole year, and the winter season is just as efficacious in the treatment of this disease as are the milder seasons of the year. The climate in general is that of Central Europe, with the addition of the peculiar influence of the mountains and the thick fir forests. The elevations of the climatic resorts are from one to two thousand feet. In this country comparable resorts are such places as Rutland, Mass., Saranac in the Adirondacks, and Liberty, N. Y.

Baden-Baden (650 feet) lies at the entrance of the Black Forest from the north, six miles from the Rhine, and is beautifully situated; it is surrounded by hills thickly wooded with the dark fir. It is one of the most popular spas of Europe, and, besides its permanent population of 15,000, it is visited in the summer by about 60,000 people. Moreover, the environs of Baden are most charming, and one can either begin or end a tour of the Black Forest at this point.

The average temperature of the year is 48.3° F., and for the summer as follows: May, 53.9° F.; June, 60.2° F.; July, 62.9° F.; August, 62.2° F.; September, 56.6° F. For the autumn, 47.6° F.; winter, 34.3° F. The yearly rainfall is quite large. The surrounding hills afford shelter from the cold winds in winter, but in midsummer they prevent the cool breezes from mitigating the heat which, for some persons, is too great for comfort.

The waters contain sixteen grains of common salt to the pint, at a temperature of 110° to 154° F. They are used for drinking, but chiefly for bathing, and in various forms of douches. The maladies for which such waters are recommended are rheumatism, gout, lithæmia, gastric catarrh, catarrh of the bladder, scrofula, chronic metal poisoning, obesity, and chronic catarrhal affections of the respiratory tract. The effect of the waters when drunk is diaphoretic, diuretic, and laxative. The bath establishments are extensive and well appointed, some of them luxuriously so, and include hot-air, vapor, pine, electric, and mud baths, and swimming pools. There is also an inhalation establishment, and a section for Swedish massage and mechanical gymnastics. There is an elaborate and extensive *Conversations-Haus* with pleasant grounds, and near at hand is a *Drink-halle*, most frequented in the early morning, when the waters are drunk to the accompaniment of music, the usual custom in European spas. There are also several private sanatoria under competent direction. The sanitary condition of the city is satisfactory, and the water supply for domestic purposes comes from mountain wells. The accommodations are abundant, excellent, and of varying price. The baths are open all the year, although they are most frequented during the season (May to October). There are also milk, herb, and grape cures. The situation of Baden with its hills affords opportunity for the "Terrain-Cur." One can also make an "after-cure" here after a course of more active mineral waters.

East of Baden-Baden, in the northeastern part of the Black Forest, is Wildbad (1,410 feet), a much-frequented spa, containing indifferent thermal waters, of a temperature of 91.8° to 104.5° F., used very largely for bathing, although they are also used for drinking and gargling. The town, of about 3,000 inhabitants, lies in the narrow wild valley of the Enz, surrounded by hills covered with pines, and possesses an agreeable climate and excellent drinking-water. The mean yearly temperature is 46.5° F., and the mean monthly temperatures for the season are: May, 53.7° F.; June, 60.8° F.; July, 63.1° F.; August, 62.6° F.; September, 55.9° F. The waters are beneficial for the class of cases for which simple hot baths are appropriate, such as chronic rheumatism, gout, chronic joint pains, metal poisoning, scrofula, functional nervous affections, catarrh of the respiratory organs, nervous dyspepsia, convalescence from acute and chronic diseases, certain gynæcological affections, and chronic skin eruptions. The bracing mountain air found here also enhances the value of a visit to this resort. The application of the waters is chiefly in bathing, and they are conducted from the wells in a continual stream at their natural temperature. There are also electric, steam, and hot-air baths; massage and gymnastics. There are several bath establishments, the property of the Government, two excellent ones, the Great Bathhouse and the König Karls Bad, and others for the poor or those of slender means. There are a variety of outdoor amusements, such as fishing, shooting, and tennis; and, as in almost all these resorts so largely visited by English and Americans, an English church.

Not far from Wildbad is Schömberg (2,180), where is situated a sanatorium for pulmonary tuberculosis conducted by a physician formerly attached to the Falkenstein Sanatorium, and in a similar manner.

St. Blasien (2,580 feet), in the southeastern part of the Black Forest, has an excellent climate and situation, affording mountain and forest air, and is resorted to both in summer and in winter. There are pleasant walks among the forests in the neighborhood, and the paths are arranged for the "Terrain-Cur." There is a well-known sanatorium here, open the whole year for the open-air treatment of pulmonary tuberculosis.

At Nordrach (1,470 feet), near the centre of the Black Forest, is Dr. Walther's celebrated "Nordrach-Colonie," in a protected position, looking toward the south. The success of Dr. Walther in the treatment of pulmonary tuberculosis has given this place and name a world-wide fame; with the English, especially, this sanatorium is very popular, and the sanatoria, now so frequently being established in England, follow Dr. Walther's methods, and sometimes take the name "Nordrach."

The climate at all these open-air resorts in the Black Forest is practically the same: the air is fresh and pure, fairly dry and equable, and although cold in winter (mean winter temperature, 29.6° F.) it is sunny and there is protection from the wind. The mountain influence is also apparent, and the thickly wooded character of the country is not without value.

Badenweiler (1,450 feet), in the lower part of the Black Forest, is a popular summer resort and spa, and possesses great beauty of situation and an excellent climate, pure air with a moderate humidity of seventy per cent., and an equable, mild temperature. The mean average monthly temperatures are: May, 53.8° F.; June, 61.5° F.; July, 64.6° F.; August, 62.8° F.; September, 57.4° F. The yearly rainfall is about forty inches. Badenweiler is used much more for a climatic health resort than for its waters, which are indifferent thermal (of 84° F.). They are used in drinking, in gargling, and in baths; and for various maladies—gout, rheumatism, neurasthenia, chronic neuralgia, diseases of the skin, catarrh of the respiratory passages, dyspepsia, dysmenorrhœa, etc. There are two public bathing pools, the "beautiful marble bath," an open swimming pool, and bath-rooms in a number of hotels. The baths are sometimes artificially heated, and common salt is added to render them more stimulating. The milk and whey cures can also be taken here. The sanitary conditions of the town and the water supply are good. There is also a steam disinfecting apparatus. The accommodations are good in hotels and pensions. In the vicinity of Badenweiler are various resorts of different elevations which offer favorable climatic conditions.

Rippoldsau (1,856 feet) is situated in about the centre of the Black Forest near the Kniebis Mountains, in a thickly wooded valley, with typical forest scenery, rocky precipices, cascades, and the ever-present fir trees. The waters are gaseous chalybeate, containing bicarbonate of iron, sulphate of sodium, carbonate of calcium, and free carbonic acid gas. The waters are taken internally in anæmia, chlorosis, debility, dyspepsia, catarrhal conditions of the stomach and bowels, etc. Iron baths are also used from two springs containing a small amount of iron and rich in carbonic acid gas. Mud baths are used extensively here, and are said to be effective in chronic rheumatic swellings, various sexual disturbances such as amenorrhœa, spermatorrhœa, and impotence. There are also pine-needle, electric, and sand baths, with massage and gymnastics. The baths are heated by Schwarz's method, which consists of the introduction of steam into the double bottoms of the separate baths. There are two well-appointed bathhouses containing twenty-five bathrooms. The yearly average is about thirty-five hundred baths. The water from some of the springs, viz., Josef's, Leopold's, and Wenzel's, are bottled and largely exported, as is also the salt (Rippoldsau salts). The accommodations are good. The rural simplicity of the place remains, many of the old-time costumes being still worn by the natives.

There are numerous other small spas and climatic resorts in the Black Forest, all attractively situated and affording opportunities for hydrotherapeutic treatment or open-air life in a fresh invigorating atmosphere. Indeed, a walking, bicycle, or automobile tour through this most picturesque region may well be considered a cure in itself for tired nerves and the mentally overworked; and the writer, from personal experience, can bear witness to the charm and restfulness of such an excursion: the air is so fresh and invigorating, the food so good, the country scenery so attractive, and the singing of the skylarks so sweet and seductive.

Edward O. Otis.

BRONCHIECTASIS.—Dilatations of the bronchi, either diffuse or circumscribed, are known as bronchiectases. They are of common occurrence and arise from a great variety of causes. In all cases, however, the essential cause of bronchial dilatation is to be found in a weakness of the bronchial wall or an increase of pressure within the bronchus, or in a combination of both these factors. Bronchiectases appear both clinically and pathologically in such a variety of forms that their classification is difficult. According to their etiology they may be divided into the following forms:

Bronchiectasis.
1. Congenital.
2. Atelectatic.
3. Vicarious.
4. Emphysematous.
5. Inflammatory.

GENERAL MORBID ANATOMY.—The condition of bronchial dilatation may be single or multiple, one or more of the bronchi being affected. In some cases the entire bronchial tree is dilated (*universal bronchiectasis*). When but one bronchus is dilated the condition is usually found in the upper lobes; when many are dilated the lower lobes are affected. Usually the bronchial branches of the third or fourth order are the ones involved; they not infrequently become wider than the main bronchi, and may often be followed out to the pleura, where they end generally in a sac-like terminal dilatation of somewhat greater width, as is seen in Fig. 5118, *b*). In other cases the terminations may be of normal width, or they may become narrowed. The smaller bronchi may at times alone be dilated, the lung on section resembling a very porous cheese.

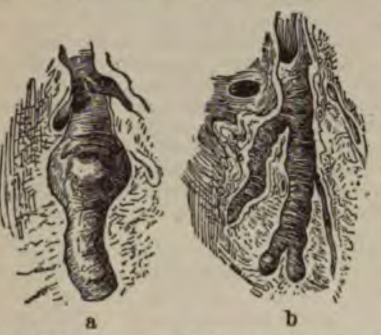

FIG. 5118.—Saccular and Cylindrical Forms of Bronchiectasis. (After Orth.) *a*, Saccular form; *b*, cylindrical form.

The dilatation may be more or less uniform (*cylindrical, fusiform*, or *spindle-shaped bronchiectasis*), or it may be localized, the dilatation being much greater at one point than elsewhere, or involving but a small portion of the bronchus (*saccular bronchiectasis*). In other cases a succession of dilated portions may be separated from each other by portions of the bronchus which are of normal width or are constricted (*varicose* or *rosary bronchiectasis*). The different forms may be found in the same lung. Closure of the central end of the dilated portion and the accumulation of secretions may give the dilatation the character of a cyst (*bronchiectatic cyst, cystic bronchiectasis*). Suppuration of the wall of the dilated bronchus gives rise to the conditions known as *ulcerative bronchiectasis* and *bronchiectatic abscess*. Enlargement of the bronchiectasis at the expense of the surrounding lung tissue leads to the formation of bronchiectatic cavities (*cavernous bronchiectasis*). Infection of the dilated bronchus with putrefactive organisms causes a *gangrenous bronchiectasis*. In this case also the destruction of the wall of the dilatation and the encroachment upon the surrounding tissue give rise to the formation of cavities. In some cases the larger bronchi may be chiefly affected, in which event the distended portions project from the main bronchus like the dilated fingers of a glove.

The walls of the dilated portion may appear to be normal, or they may show marked pathological changes. The inner lining may be smooth or roughened. The smooth-walled dilatations often contain no fluid. As a rule the bronchial mucosa presents the appearances of a chronic purulent catarrh. The cylindrical epithelium is usually replaced by one of a cubical or squamous type. In the large saccular bronchiectases and in some of the cylindrical forms due to retained secretions the lining membrane may be ulcerated. Polypoid outgrowths are not infrequently seen. The contents of the cavity may be thin and watery, or thick or even caseous. In some of the larger bronchiectases, and particularly in the case of secondary gangrene, the contents are horribly fetid. Microscopically the fluid consists of mucus, pus corpuscles, fatty acid crystals, and occasionally blood and hæmatoidin crystals. In the case of ulcerative or gangrenous conditions of the walls elastic fibres may also be present. The outer portions of the wall of the dilated portion may be markedly atrophic; even the cartilage plates may entirely disappear. The elastic tissue is stretched and separated; and the muscle, if it has not entirely disappeared, is much stretched and atrophied. The mucous glands may also entirely disappear, or may show extreme mucous degeneration. In other cases a secondary thickening of the wall, due to a new formation of connective tissue and elastic fibres, may occur. This is true particularly of the inflammatory cases. Small-celled infiltration of the wall is usually present. According to the condition of the bronchial wall bronchiectases may be divided into the *atrophic* and the *hypertrophic* forms. Such a classification has, however, but little practical importance, inasmuch as both forms may be found in the same lung. In general, the condition of the wall is dependent essentially upon the cause of the dilatation.

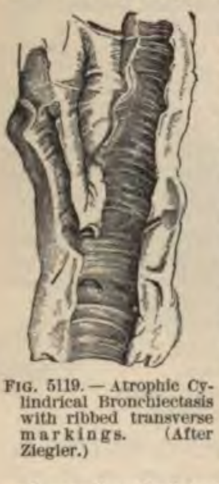

FIG. 5119.—Atrophic Cylindrical Bronchiectasis with ribbed transverse markings. (After Ziegler.)

The *atrophic form* occurs in association with emphysema, and as a sequela of old chronic inflammatory processes which lessen the elasticity and resisting power of the bronchial wall, so that it gives way to the air pressure. Prolonged and difficult expiration favors its occurrence. Such dilatations are usually cylindrical and occur chiefly in the bronchi of the lower lobes. Very often the stretching of the bronchial wall is not uniform, and the inner surface shows circular or oblique ribbed elevations corresponding to circular bands of muscle fibres and elastic tissue which are still preserved, the connective tissue between them being pushed outward. All the elements of the wall are more or less atrophic, even the cartilage, which may be replaced by connective tissue containing newly formed blood-vessels. The openings of the mucous glands are dilated and funnel-shaped. The epithelium may be well preserved, or it may be changed to a cubical or flattened variety, or may be desquamated.

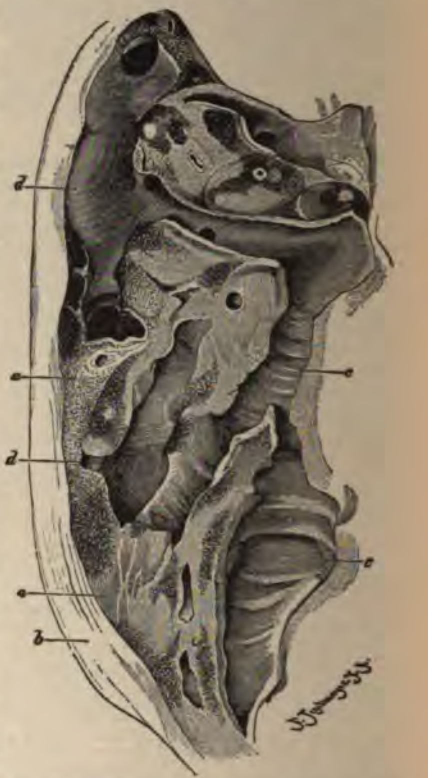

FIG. 5120.—Hypertrophic bronchiectasis and bronchiectatic caverns in fibroid induration of lung. (After Ziegler.) *a*, Indurated lung tissue; *b*, thickened pleura; *c*, dilated bronchus; *d*, cavity communicating with a dilated bronchus.

The *hypertrophic* form occurs as a frequent sequela of indurations and contractions of the lung parenchyma. In these cases the greater part of the lung is usually impermeable to air, and the cause of the dilatation is less a result of the weakening of the bronchial wall, but is essentially dependent upon an increase of intrabronchial pressure, which is due to the fact that the air entering the bronchi no longer passes normally into the ramifications of the air passages. In the case of retraction of the lung tissue with pleural adhesions the outward pull upon the bronchial walls is also an important factor in causing a dilatation of the bronchial lumen. In both cases the dilatation is favored by any inflammatory process which weakens the wall. The mucous membrane of the dilated bronchus in the hypertrophic mass may resemble that found in the atrophic forms, or papillary or polypoid proliferations may be present. A lattice-like marking of the lining membrane is often seen. These markings correspond to small thickenings or elevations of the mucosa corresponding to the formation of a very cellular granulation tissue about the longitudinal and transverse bundles of elastic tissue. The connective tissue of the wall and of the peribronchial region is more or less thickened and connective tissue may take the place of the mucous glands and cartilages. The capillaries of the wall are greatly dilated and present thickened walls. The hyperæmia of the wall may be so marked that the appearance of the mucosa suggests a hemorrhagic condition. Tuberculous and gangrenous processes may cause various modifications of these appearances.

The *saccular* bronchiectases usually develop at the cost of the lung parenchyma. The bronchus may show at some point in its course a dilatation varying in size from that of a mustard seed to that of a hen's egg, or the bronchus may terminate in a sac. The central end of the dilatation may become obliterated and the dilatation thus come to resemble a cyst. Through the accumulation of secretions the cyst may attain great dimensions. All the bronchi of one lung may be similarly affected, the lung tissue between becoming atrophic and compressed, so that the organ finally comes to resemble a multilocular cyst. In other cases the saccular dilatation may involve only a portion of the circumference of the wall, so that it appears as a diverticulum which is connected with the lumen of the bronchus by a narrow opening only (*dilatation ampullaire latérale* of Cruveilhier). In the majority of cases the saccular dilatations involve the smaller bronchi, more rarely are the main branches affected. They are usually associated with bronchial stenoses, and are most often found near the periphery of the lung. According to Gairdner all the saccular dilatations are the result of ulcerative excavations of the lung tissue. This is true, however, of only a part of the cases.

Biermer divides bronchiectases, according to the character of their walls, into the following forms: (1) Dilatations with catarrhal swelling and relaxation of the bronchial wall. These are acute and occur chiefly in the lungs of children affected with chronic bronchitis. After the bronchitis has been cured the bronchial wall regains its old tone and elasticity, and the dilatation disappears. (2) Dilatations with hypertrophic walls. These affect the larger bronchi and are usually spindle-shaped. (3) Dilatations with thin walls. These are usually saccular. (4) Dilatations with trabecular degeneration. The walls are uneven, thickened, and there is a peribronchial increase of connective tissue.

Ulcerative processes are of common occurrence in the mucosa of the saccular bronchiectases. Complete destruction of the elements of the wall may take place, giving rise to a bronchial abscess. Infection with putrefactive bacteria leads to a secondary gangrene. Such changes are due to the lessened resistance of the bronchial walls, the changes in the secretions, and the entrance of bacteria. In these cases elastic tissue may be found in the sputum. Deposits of lime salts may occur in the bronchial walls, and as the result of the formation of granulating surfaces adhesions of the walls or the development of connective-tissue bridges may take place. In some cases a complete obliteration of the lumen results, and the bronchus is converted at the point of dilatation into a fibrous cord.

The changes in the lung tissue in the neighborhood of the bronchiectasis are usually primary, with the exception of ulcerative and gangrenous processes, which are secondary to the dilatation. The bronchi which are not dilated show catarrh and a putrid decomposition of the secretions. They are often wholly obliterated. In bronchiectases due to syphilitic affections of the air passages the dilatation of the smaller bronchi is usually secondary to a stenosis of the trachea or large bronchus. The portions of the lungs not affected by the condition causing the bronchiectasis may present a compensatory emphysema, and in the later stages foci of bronchopneumonia, due to the aspiration of secretions from the dilated bronchi, may be found. The right ventricle may become hypertrophied and dilated as the result of the stasis in the pulmonary circulation. The bronchial glands are usually swollen.

Metastasis may take place from bronchiectases. Biermer observed metastatic brain abscesses in four cases of bronchiectasis; and Gerhardt and Bardenheuer noted the occurrence of rheumatic joint affections in patients with bronchiectases. Chiari has reported a case of suppurative myelitis following bronchiectasis. In the pus and vessels of the cord a branching filamentous fungus was found which showed threads breaking up into coccoid bodies and staining with Gram's mixture. Of eight cases of hæmatogenous myelitis collected from the literature three were secondary to bronchiectasis. In one case of actinomycotic abscesses occurring in the brain of a man with numerous bronchiectatic cavities, many clusters of the fungus were found in the walls and contents of the latter.

Location.—Statistics as to the location of bronchiectases are of doubtful value. This is particularly true with regard to the relative frequency of involvement of the right and left sides and the upper and lower lobes. The statements generally made in regard to these points are to the effect that bronchiectases usually occur in one lung, and more frequently on the left than on the right side, and more often in the upper lobe than in the lower, and that in double-sided bronchiectasis both upper lobes are more often affected than the lower ones. But little importance can at present be attached to such statements, the number of observations upon which they are based being too small. The dilatations occurring with tuberculosis and chronic inflammatory processes are more often seen in the upper lobes; in the case of pleuritic exudations, in the compressed lower lobes; in those occurring as sequelæ of croupous and catarrhal pneumonia, hypostatic and atelectatic conditions are found in the lower and posterior portions. In the case of pleural adhesions the dilatations are sometimes found in the bronchi of the upper lobe, sometimes in those of the lower lobe.

Congenital Bronchiectasis.—Under this head there is included a number of conditions in the lungs of the newborn which have been regarded as due to congenital syphilis. One lung is usually affected; it may contain numerous cysts filled with a serous fluid. The lung tissue between the cysts may be indurated or atelectatic. Heller, Herzheimer, Grawitz, and others have described cases which, according to Grawitz, are to be ascribed to a hydropic dilatation of the bronchi. Heller regards them as representing the bronchi of undeveloped portions of the lung, the dilatation occurring in later life partly as the result of the growth of the thorax and the consequent pull upon the bronchus, and partly as the result of the growth of the bronchus itself and the pressure of retained secretions.

Atelectatic Bronchiectasis.—The congenital bronchiectasis of Heller is to be placed in this class. In a number of cases observed bronchial dilatations have been found in adults, the lung tissue being free from pigment and showing no evidences of inflammatory changes. The condition is therefore very probably the result of a congenital atelectasis. An acquired bronchiectasis, due to atelectasis, may take place in later life as the result of deformities of the thorax, tumors, aneurism, etc.

Vicarious Bronchiectasis.—If the entrance of air into any portion of the lung be hindered and the volume of that part reduced, the inspiratory pull upon the sound portions of the lung is increased. As the result of this increased pull both the alveoli and the bronchi become dilated, and there arise a vicarious emphysema and a vicarious bronchiectasis. Pneumonic foci, infarcts, local atelectasis, local tuberculous nodules and infiltrations, contracting scar tissue, etc., are the causal factors of such bronchial dilatations. The bronchial wall and mucosa become stretched and thinned like a serous membrane The essential characteristic of the change is that no inflammatory processes take part in the direct production of the dilatation. It is to be regarded as a vicarious emphysema of the bronchi. The clinical significance of the condition is not great. The dilatations are relatively small and circumscribed. Inflammatory changes may follow, and an ulcerative or inflammatory bronchiectasis develop.

Emphysematous Bronchiectasis.—An emphysema of the bronchi occurs also in simple atrophic emphysema of the lungs not due to a compensation for portions of the lung the function of which is lost or diminished. It is to be regarded as idiopathic rather than vicarious or compensating. The dilatation is not great, but the walls of the bronchi are greatly thinned. The smaller branches, particularly those of the lower lobes, are chiefly affected. The symptoms cannot be separated from those of alveolar emphysema.

Inflammatory Bronchiectasis.—This is by far the most common and important form. All authorities are agreed that for the production of a bronchiectasis of clinical importance an inflammatory weakening of the bronchial wall is necessary. In general there are no severe inflammatory conditions of the lungs or pleura in which bronchiectases may not develop. Capillary bronchitis, chronic bronchitis, catarrhal pneumonia, croupous pneumonia, particularly when running a subacute or chronic course, tuberculosis, obliteration of the bronchioles due to indurations, peribronchitis, typhoid hypostasis, stenosis of the large bronchi, pleuritis, pleural adhesions, etc., are the causal and predisposing factors. General anæmia, marasmus, alcoholism, excessive or forced respiratory movements, singing, screaming, coughing, etc., play a secondary part. In the case of bronchial stenoses the bronchus is usually dilated both above and below the point of stenosis. It is probable that the dilatation which lies below the stenosis is due to the fact that the air which passes through the stenosis into the portion of the bronchus below it is held there by the blocking of the stenosis with mucus during expiration, and as the result of the expiratory increase of pressure this portion of the bronchus becomes stretched. In the case of foreign bodies the bronchial dilatation is found not only around the body, but involving other bronchial branches as well. The causes of such dilatations are complicated, but the essential factor is the production of a peribronchitis. Tuberculosis and syphilis may give rise to bronchiectases which are primarily dependent upon stenoses caused by the contraction of scar tissue, or are due to infiltrations. Chronic pneumonia, whether following the acute pneumonias, or due to syphilis, pleuritis, foreign bodies, etc., or primary of unknown origin, is of especial importance in the etiology of bronchiectasis.

SYMPTOMS.—*Cough.*—This is the rule. It occurs in paroxysms, usually at long intervals, almost always on the patient's awakening in the morning, the paroxysm being repeated once or several times during the day. The patient may be awakened by the first paroxysm, or it may come on after arising. Usually the patients know the time when the attacks may be expected. A paroxysm may also be precipitated by the patient's lying upon the affected side and then turning suddenly into another position. The attacks are often very violent and convulsive, at times completely depriving the patient of breath. The frequency and severity of the cough are dependent upon the position and the character of the opening of the dilatation. As long as the secretions are retained within the cavity there is no coughing, but when these escape into the neighboring bronchi and alveoli paroxysms are excited. When the bronchiectasis is located in the apex the secretions may pass continuously into a vertical bronchus and thus give rise to almost constant coughing.

Dyspnœa.—This may be slight or entirely absent; it usually increases in degree toward the later stages of the affection and may become very marked. Ordinarily it is noticed only at the time of coughing, or after vigorous exercise. It is increased in the event of acute catarrhs of the respiratory tract, and in the case of the collection of mucus in the smaller bronchi. Persistent dyspnœa is due to some complication on the part of the heart or lungs.

Expectoration.—The attacks of coughing are attended by expectoration. This may resemble that of any ordinary bronchitis, but in the majority of cases the expectoration is very characteristic and of diagnostic importance. With the coughing paroxysm there is a gush of sputum so great as to fill the patient's mouth. Within a few minutes an ordinary sputum cup may be entirely filled. The total amount of sputum may be so great as to suggest the possibility of the perforation of an empyema into the bronchus or lung. Five to seven hundred cubic centimetres may be expectorated within the twenty-four hours. With the evacuation of the dilatation the coughing usually ceases, to begin again as soon as the bronchiectasis fills up. Usually the sputum is raised easily, without much effort or coughing, but in the case of such complications as pleuritis, emphysema, tracheal or bronchial stenosis, etc., the expectoration may be very difficult. The position of the patient is of great importance; when he lies upon one side there may be neither cough nor expectoration, but as soon as he turns upon the other side the bronchiectasis begins to empty itself and the cough and expectoration are excited. Sensations of pressure, fulness, and pain are sometimes felt before the expectoration takes place, particularly in the case of children. Occasionally these symptoms may be very marked, lasting half an hour or so before the expectoration occurs. The large amounts of sputum and the long periods between the attacks of expectoration may be explained as due to a lessened irritability on the part of the bronchial mucosa, a larger quantity of sputum being necessary to excite coughing. The amount of sputum raised is always greater during the morning hours. Toward the end of the affection the total amount decreases as the patient becomes weaker.

Sputum.—The sputum is usually purulent in character, but may be fetid or gangrenous. When purulent it is yellowish and contains more or less mucus. If fetid in character the odor may be extremely disagreeable and penetrating, so that the patient's breath may be perceived some distance away. The patient himself shows a remarkable tolerance of the odor; nausea is rarely produced. In the gangrenous cases the sputum is grayish-yellow or greenish in color. When the complication of gangrene is not present the sputum may have no putrid odor, but commonly possesses a disagreeable, nauseating, acid or sweetish smell (pseudogangrene). When collected in a glass or cylinder the sputum separates into two distinct layers: an upper, thin, slightly cloudy, almost serous layer; and a lower, thick, purulent layer containing caseous masses. The latter appear as dirty yellow plugs varying in size from a mustard seed to a bean (plugs of Dittrich). If the sputum be put into a tall cylinder which is half filled with water, four distinct layers may be seen. The uppermost is foamy; the one beneath this consists of muco-purulent masses, which hang down in the form of shreds into the third layer, consisting of cloudy water. The lowest layer of water has a grayish-green appearance.

Microscopically the sputum is made up of pus corpuscles which may be well preserved or contain fat droplets. In the case of putrid decomposition bacteria, crystals of fatty acids, margarin, tyrosin, leucin, and triple phosphates may be present. Blood pigment may also be found. In the case of gangrene elastic fibres may be present. The caseous plugs stain a brownish-yellow, blue, or violet with dilute iodine solutions. The mucin content of the sputum varies greatly. Blood cells are not infrequently present.

Hemorrhage.—The presence of blood in the sputum of bronchiectasis is not rare. The amount is usually small, but the hemorrhage may be so large or so frequently repeated that severe symptoms or even death may ensue. The sputum in such cases may appear to be chiefly blood; it is rarely bright-red, but is more or less discolored by the mixture with the other elements of the sputum. The smaller hemorrhages are chiefly of capillary origin; the large ones come from the erosion of large vessels in the wall of the dilatation. In ulcerative conditions of the wall the hemorrhages may be very severe, persist for a long time, and finally lead to death.

General Symptoms.—When secondary changes in the heart, kidneys, etc., are not present, the general condition of the patient may be quite good or fair. Fever and sweating are signs of complications. Occasionally fever may be caused by the absorption of products of decomposition from the cavity. In such cases the fever does not present any distinct type.

Physical Signs—Inspection.—The color of the skin is usually unchanged. When it is very pale the underlying disease is most likely to be tuberculosis; when it is cyanotic there is usually emphysema present. Many of the patients lie upon their backs; others sit bending forward, claiming that this prevents the swallowing of the sputum. When the bronchiectasis is confined to one side, the patients usually lie upon the affected side, coughing and profuse expectoration being caused by turning upon the sound side. Deformities of the thorax are rare, occurring only in the case of retraction of the lung, or when extensive pleuritic adhesions are associated with the bronchiectasis. Diffuse or localized retraction of the thoracic wall and curvature of the spine may result from these conditions. When emphysema is present the thorax may present the characteristic barrel form. Occasionally differences of movement may be made out between the two sides. In the case of extensive bronchiectases of the lower lobe of of one side there may be seen during deep inspiration a wave-like retraction of the intercostal spaces proceeding from above downward. On the affected side such a movement is not visible. A compensatory emphysema of the sound lung is always found in such cases. Very rarely it may be seen that the respiratory movements on the affected side lessen, and at last wholly cease as the bronchiectasis fills up, but return after the expectoration has emptied the bronchus.

Among the most common and important of the physical signs of bronchiectasis are the changes which take place in the distal phalanges of the hands and feet (drumstick fingers). The clubbing of the fingers is due to a hypertrophy of the terminal portions of the bones (ostéoarthropathie hypertrophiante pneumique), so that the joints of the phalanges, the carpal joints, and even the wrist joint may be greatly thickened. These changes take place in association with chronic cyanosis and appear to be dependent upon the latter. They are also found in other conditions than bronchiectasis, particularly in the congenital heart lesions; but Bamberger has attempted to show that the change in bronchiectasis is characteristic of this affection, in that it is a painful hypertrophy of the epiphyses.

Percussion.—The percussion phenomena of bronchiectasis vary greatly, being dependent upon the size of the dilatation, the quantity of fluid present in it, its distance from the chest wall, and the character of the changes in the surrounding lung tissue. Dulness or a tympanitic tone may be obtained, or both alternately, according as the cavity contains fluid or air. A tympanitic tone with change of pitch on opening and closing the mouth may be noted, as well as change of tone on change of position, the cracked-pot sound, metallic tones, etc., according to the conditions present. About the areas showing such signs of cavity the tone may be resonant; in the case of tuberculous cavities it is always dull. The dislocation of the neighboring organs, pleuritic thickenings, adhesion, etc., may also be shown by percussion.

Auscultation.—The vesicular murmur is weakened or absent, being replaced by a bronchial blowing. The cylindrical dilatations give a soft bronchial sound, and when containing fluid they yield also moist, coarse bubbling râles. The saccular dilatations give both the percussion and auscultation signs of a cavity, particularly large, moist, bubbling râles.

COMPLICATIONS.—The most frequent and dangerous complication is the putrid or gangrenous decomposition of the contents of the dilatation. Pleuritis, peribronchitis, bronchopneumonia, chronic pneumonia, chronic bronchitis, lobar pneumonia, emphysema, chronic laryngitis, renal and cardiac affections, dropsy, albuminuria, cirrhosis of the liver, etc., may be associated with bronchiectasis or appear as sequelæ. Metastatic abscesses may occur in the brain, spinal cord, etc.; there may also be rheumatic joint affections. There arises in these cases a suspicion of the occurrence of a general pyæmic infection. Perforation of the dilatation into the pleural cavity leads to the development of a pyopneumothorax. In old chronic cases of long duration amyloid degeneration of liver, spleen, and kidneys may be found. Tuberculosis is a fairly common complication. The heart is usually affected, hypertrophy and dilatation of the right ventricle occurring in the majority of cases. The cardiac changes are due partly to disturbances in the pulmonary circulation, partly to the accompanying condition of chronic intoxication, partly to local changes in the thorax, and partly to coincident renal changes.

DURATION AND COURSE.—Bronchiectases may remain stationary for years, the only symptoms being those of a chronic bronchitis. As a rule the dilatation gradually increases during this time without an increase in the symptoms. With the advent of fresh catarrhs emphysema gradually develops, the shortness of breath becomes more marked, and the patient may become cyanotic. The right heart becomes hypertrophic and finally dilated. Putrid bronchitis and gangrene may occur; from these the patient may recover for a time, or death may take place. As a rule the condition runs for a long time; amyloid disease of the kidneys may finally result and the patient becomes dropsical. After alternating periods of improvement and exacerbation, extending over a long period, the disease is brought to an end by some one of the complications.

DIAGNOSIS.—The differential diagnosis of bronchiectasis from its complications is sometimes very difficult. The absence of the tubercle bacillus will distinguish it from tuberculosis. When the latter process is combined with bronchiectasis the character of the sputum, the age of the patient, position of the cavity, habitus, etc., are points to be considered in the differential diagnosis. The history of the case is of greatest importance. It may be taken as a guiding principle that tuberculosis may lead to a bronchiectasis, but that a bronchiectasis rarely becomes tuberculous. Actinomycotic cavities may be distinguished by the presence of the fungus in the sputum. The rare localization in the lung of hydatids may also be easily diagnosed by the findings in the sputum. From pulmonary gangrene, abscess, putrid bronchitis, interstitial pneumonia, pyopneumothorax, etc., the differentiation is often impossible. The physical signs of cavity are of the greatest importance in so far as the differentiation between processes with cavity formation and those without is concerned. Much was expected from the use of x-rays in the diagnosis of bronchiectasis, but these expectations have not been realized. Only in the case of extensive peribronchial thickenings may aid be looked for by the use of x-rays.

TREATMENT.—In very rare cases self-healing of the bronchiectasis may take place. In children this may follow the cure of catarrhal bronchitis and the restoration of normal conditions of pressure. In extremely rare cases the bronchial cavity may be obliterated by adhesion of the walls of the cavity or through the formation of granulation tissue. Since in the great majority of cases such healing is impossible, the prophylactic treatment becomes of prime importance. The conditions (pleuritis, pneumonia, etc.) which lead to bronchiectasis should be appropriately treated with a view to the prevention of such dilatations. After the development of bronchiectases the chief therapeutic indication is to keep the contents of the dilatation—so far as lies in our power —aseptic. This can be perfectly accomplished only by residence in an atmosphere containing no bacteria. Removal of the patient to a suitable climate is the best means of avoiding the various complications of the affection. When this cannot be done the treatment becomes chiefly symptomatic and largely directed to antiseptic procedures. Inhalations of creosote, turpentine, menthol, eucalyptus, etc., and creosote vapor baths are recommended for this purpose. A number of writers speak favorably of the creosote vapor baths. These are, however, unpleasant and slow in operation, and do not always succeed in lessening the amount of the sputum. The crude creosote appears to be more effective than the various substitutes (vapo-cresoline, refined creosote, soluble cresol, etc.) which have been advised. Other writers have found success with guaiacol vapor baths after failing with creosote. The ordinary methods of giving such inhalations may, however, be a source of infection, as many of the forms of inhalation apparatus used are dirt traps.

Intralaryngeal injections of menthol, guaiacol, etc., have been advised by Rosenberg, Stewart, Campbell, and others, but are condemned by various writers because they give rise to constitutional disturbances, fever, and violent cough.

Subcutaneous injections of guaiacol (1 in 5) and creosote (1 in 5) in olive oil have also been recommended. They may give rise to inflammation and necrosis at the point of injection.

Intravenous injections of formalin (25–50 c.c. of a 1 in 2,000 solution of formalin in decinormal salt solution) have also been tried without success.

Injections of carbolic acid and menthol directly into the bronchiectatic cavity have also been suggested.

Murphy's method of filling the pleural cavity with air or nitrogen to such an extent as to cause a collapse of the bronchial cavity has been tried with some success. The air should of course be thoroughly sterilized. About 170 c.c. of air or nitrogen are injected every second or third day.

Inhalations of oxygen may aid in reducing the odor of the sputum. Symptomatic treatment with expectorants (apomorphine, senega, ipecacuanha, etc.) may at times give relief or temporary improvement. Hemorrhage should receive appropriate treatment.

Inasmuch as the medical treatment is usually without avail, much had been hoped from surgical intervention in the treatment of bronchiectasis. This has now been given a very extensive trial, with complete failure in the majority of cases, and only partial success in the others. These unsatisfactory results are easily understood when we consider the facts that the dilatations are often multiple and bilateral, and that the pulmonary tissue is usually extensively diseased. Dangerous hemorrhages may result, and anæsthesia is in itself attended with danger in these cases. The uncertainty of the physical signs also contributes to the unsatisfactory results. Puncture of the bronchiectatic cavity with a trocar and drainage, incision and drainage, cauterization of the cavity, etc., are among the operative procedures advised. From the cases thus treated which have been so far reported, it would seem that under favorable conditions of life the outlook for patients with bronchiectasis is more favorable without operation than with it. Improvement of the technique of operations upon the lung may lead to better results.

The *postural* treatment of bronchiectasis is strongly recommended by Ewart (*Lancet*, 1901). While not regarding it as curative in advanced cases, he holds that no other treatment is so simple, so rational, and so effective. In a case so treated the relief afforded the patient was striking; the persistent pyrexia stopped, and the gushing character of the expectoration ceased. Ewart advises a continuous elevation of the foot of the bed of from twelve to fourteen inches. For brief periods a greater elevation may be resorted to with benefit.

PROGNOSIS.—In so far as a cure is concerned the prognosis in any well-established case of bronchiectasis is bad. Except in rare cases no method of treatment at present employed is of avail in effecting a cure. Some of the more acute cases in young persons may, however, be cured. In the chronic cases our present methods of treatment can only relieve the distress of the affection and prolong life. *Aldred Scott Warthin.*

CAMPHOR, POISONING BY.—An unwarranted belief in the innocuousness of camphor prevails in the community, referable, probably, to the safety with which it is used as an external domestic remedy for minor ailments and to its agreeable odor. This should not, however, blind the physician to its real and serious dangers when taken internally; for it may act as a poison either when eaten frequently in small quantities, as for headaches or colds, or when swallowed accidentally or intentionally once or more in large amount. It is true that fatal cases are very rare, but the symptoms are often most alarming, even when recovered from. The lethal dose of camphor is difficult to determine. The smallest dose known to have produced violent symptoms in an adult is 1.3 gm.; the largest dose known to have been recovered from is 15 gm. (Kunkel, Blyth). Camphorated liniments swallowed by mistake have frequently been the cause of severe cases of poisoning, the fact of the drug being in alcoholic solution allowing it to be absorbed and disseminated through the system more rapidly and in larger quantity than when swallowed in the solid form. The histories which I shall presently cite illustrate further the usual sequence of symptoms, and such relations as the early or late supervention of convulsions to the occurrence or absence of vomiting, this depending upon whether any large proportion of what was swallowed remained long in the stomach in a comparatively insoluble condition, or was promptly taken into the circulation. Attention is also called to the statement that when camphor has been swallowed, what is absorbed undergoes such a transformation that the odor of it is not appreciable in the urine or fæces (Kunkel); sometimes not even in the breath of the patient. Still, other authorities declare that the bodies of those dying smell strongly of the drug.

Full doses of camphor produce markedly exciting effects upon the brain and the medulla, especially when an alcoholic solution has been taken which favors rapid absorption. The earliest evidences of this stimulation are flushing of the face, a rapid succession of ideas, perhaps agreeable hallucinations, with a sense of lightness of motion and a desire to dance, in fact an intoxication. These manifestations are transient and may soon be followed by tonic cramps and epileptiform convulsions. To these may succeed sometimes paroxysmal tonic and clonic cramps with movements of rotation, followed by paralysis; or again deafness passing into sopor, coma, and death, the parts of the nervous system which are first excited being apparently finally paralyzed. The temperature is lowered, but the pulse and respiration vary (Brunton, Husemann). If the patient recovers, the memory is apt to be wanting for some hours. There are no characteristic lesions after death.

The following cases are fairly typical of poisoning by camphor: Davies reports being called at 3 A.M to a child of two years and eight months, who had swallowed solid camphor. He found it pale, with blue lips, a rapid pulse, and suffering from severe convulsions. Vomiting was induced and the ejecta smelled strongly of camphor. The child soon recovered in part from its condition of collapse, but the convulsions continued, and in the intervals the patient was semicomatose. A stomach-pump was then used and the stomach washed out with warm water, procuring some relief. In five hours castor oil was given, also bromide of potassium, three grains every three hours. Still no improvement; the convulsions continued all night and the child died at 9 A.M. of the next day. The amount of camphor taken was probably half a drachm. From its being solid the stomach-pump could not act upon it effectively.

Craig reports that a man who was a hypochondriac ate about three drachms of pure camphor. About half an hour after swallowing it he was seized with giddiness and nausea, staggered on rising and seemed likely to fall. Still he was unable to vomit, and was relieved by drinking some water. He was free from pain, and lay down with a drowsy ringing in the ears. In three-quarters of an hour the giddiness and nausea had gone, but he felt as if he had been taken from his feet and were being carried through the air. He sat down at the dinner table, but became suddenly unconscious. He had general convulsions, which soon ceased, and the reporter says there was no deviation of the eyeballs, pupils equal and small and not reacting to light, knee-jerks exaggerated; breathing rapid, cyanosis followed by pallor. He was not unconscious for over five minutes. There was no odor of camphor in the breath. About two hours and a half after taking the camphor he vomited copiously, and brought up no blood and some camphor. There was no retention of urine. His memory was affected for an hour after other symptoms had disappeared.

Honman reports the case of a girl of eighteen, to whom he was called at 11 A.M. She was in the habit of eating camphor. He found her unconscious and irritable, with dilated pupils, cold extremities, pale face, epigastrium sensitive to pressure, pulse thready and uncountable, and the breath smelling distinctly of camphor. The stomach was washed out after an unsuccessful attempt to produce vomiting by sulphate of zinc. Ether was given subcutaneously with immediate improvement. It was learned that she had had camphor in her hand, and had offered it to her roommate at bedtime. She had vomited during the night and had taken brandy and water about 8 A.M. Convulsive movements now began and extended from the lower extremities to the body and upper limbs. The temperature rose to 100.8° F., and the pupils were dilated. She died at about 8 A.M. the next day. At the autopsy the only finding attributed to camphor poisoning was a high degree of congestion of the vessels of the dura mater and surfaces of the brain. The government analyst reported a small quantity of camphor in the stomach, but it is observed that none of the ejecta or dejecta had been saved prior to the doctor's arrival at 11 A.M.

In regard to the treatment of poisoning by camphor, the most important precept laid down is the earliest possible emptying of the stomach by tube, stomach-pump, or emetic. Hypodermic injections of brandy or ether may be used, with perhaps the alternate hot and cold douche.

CANTHARIDES, POISONING BY.—The poisonous action of this drug is ascribed chiefly to the proximate principle *cantharidin*, which is from twenty-five to thirty times as active as the powder. As the unassayed powder or the tincture is the form in which it is most apt to have been taken, it is difficult to determine the fatal dose of cantharidin. Blyth states that a young woman died from twenty-five grains of the powder, probably equal to one grain of cantharidin, while the smallest dose of the tincture known to be fatal (Taylor) is an ounce, equivalent to gr. $\frac{24}{100}$ of the proximate principle. Poisonous effects may also follow from external applications of the drug, in which they result from absorption, especially in feeble persons and children. Blyth says that the popular idea of the influence of cantharides as an aphrodisiac holds good only as to the entire cantharides, and not as to cantharidin, and he considers it probable that cantharidin is not the only proximate principle in the insect. It is also stated that cantharides may be eaten with impunity by fowls, while the flesh of the latter may produce symptoms of poisoning if eaten by human beings. Ogier tells us that a fatal result may follow poisoning by this drug after as long an interval as twenty-four hours; also that proof of the cause of death may be found in the presence in the intestine of minute glistening particles of the insect. Fatal cases are rare.

The symptoms due to poisonous doses are given as follows by Husemann, Kunkel, and Blyth: They are shown in disturbances of respiration and in convulsions from involvement of the nervous system, often with headache, dizziness, stupor, and delirium. In the alimentary canal there appear at once burning in the mouth and throat followed by pain on swallowing, salivation, vomiting, and diarrhœa, while there develop intense irritation, pain, and a condition of inflammation of the kidneys and urinary passages, in consequence of which occur in the urine albumin, casts, pus, and blood, with catarrh and croupous deposits from the vesical mucous membrane. These are associated with strangury, dysuria, painful erections, and priapism. Sometimes pregnant women have aborted.

The following fatal case is reported by Lhôte and Vibert. A man of about sixty took a quantity of cantharidin, estimated at about 75 cgm. He died twelve to fourteen hours afterward, the symptoms presented not being accurately known. Autopsy four days post mortem. The lungs were much congested; there was a little froth in the bronchi. Stomach empty; mucosa actively congested. Kidneys large, turgescent, and extremely congested; several large sanguineous effusions under the capsule; cortical and medullary substances gorged with blood and the mucosa of the calices and pelvis strongly injected. Bladder contained 4-5 c.c. of bloody urine; mucosa strongly congested and of an intense red; no ulcerations but many ecchymoses. Mucosa of the urethra likewise congested. On microscopical examination of the kidneys the glomeruli were found detached from their capsules, and separated from them by an exudate, in the midst of which were seen at certain points numerous round, nucleated cells. In the convoluted tubes the epithelial cells appeared glued together; they filled and distended the tubes. A material extracted from the viscera produced upon animals the effects of cantharidin, and its chemical reactions were characteristic of that substance.

The *treatment* of poisoning by cantharides must be symptomatic. The stomach should be evacuated, the stomach-pump or tube being used for the purpose if the mouth and throat are not inflamed; if they are inflamed, apomorphine should be injected hypodermically or an emetic should be given. Opium and hot sitz baths should be used to allay pain and strangury, and water and mucilaginous drinks given freely, but fats and oils are to be avoided.

CAROTID GLAND.—(Synonyms: Ganglion intercaroticum; Glandula carotica; Glomeruli arteriosi intercarotici; Nodulus intercaroticus.)

This little-known organ lies in the bifurcation of the common carotid artery, generally near the posterior side of the internal carotid just as it comes off the main trunk. In size it is about 1-3 mm. in diameter, varying considerably. Because of its great vascularity the color is pink. For some time it was thought to be an epithelial organ developed similarly to the thyroid and thymus from the branchial clefts, but further study showed it to be of entirely different origin and nature. Its embryonal origin is later than the thyroid and thymus, and it is in no way related to them, for it arises directly from the primary vascular *anlage*, and therefore is not an epithelial but a perithelial structure. The first step in its formation consists of a cellular thickening of the external posterior portion of the periphery of the embryonal carotid. At this time the cells, of epithelioid type, are not distinguishable from the cells of the vessel wall itself, and the gland anlage is recognized merely as a thickening of the cell mass at this point. This entire nodule is surrounded by the adventitia, and over it run nerve bundles from the vagus and cervical sympathetic. Very early in its development capillary vessels derived from the common carotid at its bifurcation enter the cell mass, and soon form glomerule-like collections, which with the rapidly increasing cell growth soon distinguish the gland from the vessel.

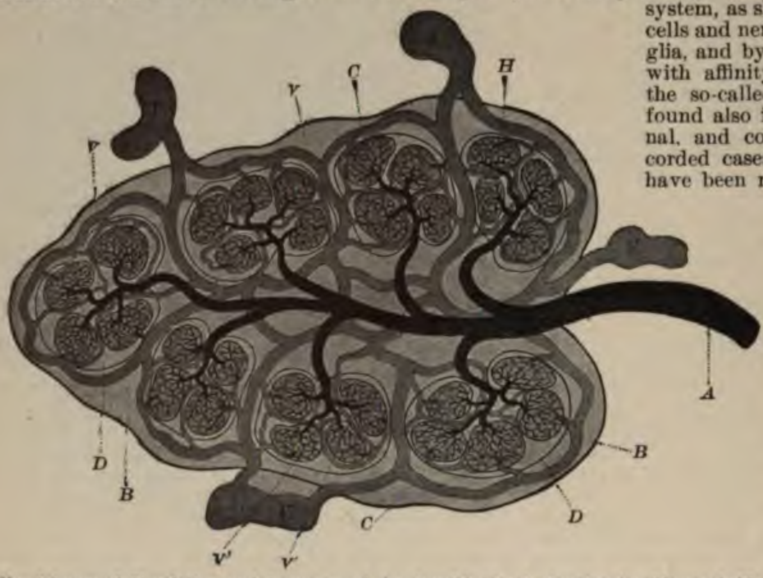

FIG. 5121.—Scheme of Circulation and Structure of the Carotid Gland, showing its Glomerule-like Character. (After Schaper.) *A*, Principal artery with *V*, corresponding vein; *B*, balls of cells; *C*, capillary networks; *D*, secondary nodules; *H*, hilus; *v*, *v'*, smaller veins.

In the adult the carotid gland shows a lobular structure. From the connective-tissue capsule bands pass into the organ carrying many vessels and nerves, and dividing it into lobules, which vary in number from three to twelve. In turn the lobules are composed of small "cell balls," which really form the unit of its structure. These consist of a glomerule-like tuft of capillaries that unite to form a vein. Surrounding the capillaries are the cells of the organ, arranged in cords or trabeculæ, although this arrangement is not at all evident in ordinary preparations. The number of cells about individual vessels varies greatly; sometimes there is quite a wall of epithelioid cells, with finely granular cytoplasm, oval nucleus, and a nucleolus, but often there is but a single layer of cells about a vessel, or the vessels may be separated merely by a loose reticular interstitial connective tissue. In this reticular tissue are frequently single cells of the same type. Often the parenchyma cells show a considerable degree of vacuolization, particularly in the old. It is said that with age the typical structure becomes less and less evident, accompanied by more or less disappearance of these special cells. The structure of the carotid gland is quite similar to that of the coccygeal gland.

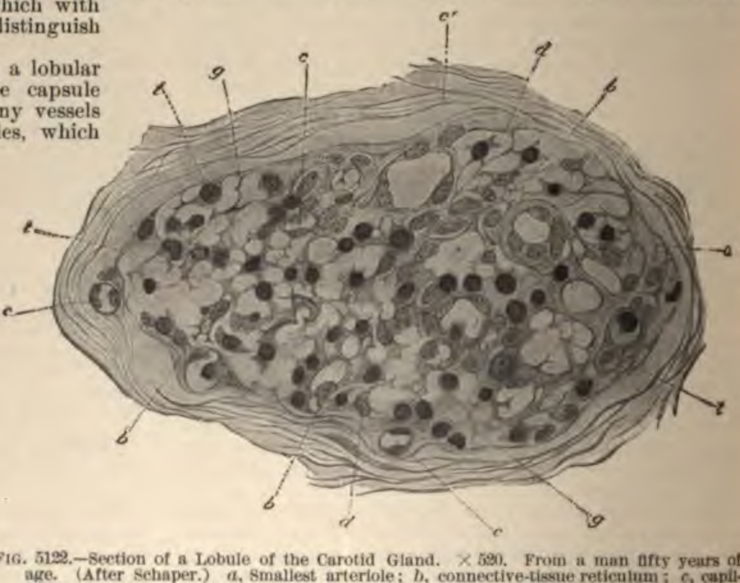

FIG. 5122.—Section of a Lobule of the Carotid Gland. × 520. From a man fifty years of age. (After Schaper.) *a*, Smallest arteriole; *b*, connective-tissue reticulum; *c*, capillaries; *d*, nuclei of stroma; *g*, protoplasmic network; *t*, nuclei of gland cells.

The function of the carotid gland is altogether unknown. It seems to have been the subject of but little investigation except by histopathologists. It is undoubtedly closely related to the sympathetic nervous system, as shown by the number of ganglion cells and nerve fibres from the cervical ganglia, and by the presence of the same cells with affinity for chromic acid and its salts, the so-called "chromophile" cells that are found also in the sympathetic glands, adrenal, and coccygeal gland. In the few recorded cases of tumors of this gland there have been no symptoms that could be considered indicative of any function, and the unilateral resection of the gland in these cases has been followed by no symptoms whatever. Extracts from the gland are said to raise the blood pressure greatly.

PATHOLOGY. — Except for tumor growths there seem to be no records of pathological alterations in this organ, probably because it escapes observation through its location and its minute size. There are in the literature eight cases of tumors of the carotid gland, all primary. They are characterized by their location in the crotch of the carotid, and by their peritheliomatous structure. They have appeared mostly about the thirtieth year, in either sex. In one instance the onset seemed closely related to fracture of the lower jaw in a tooth extraction. The growth is usually slow, in one about thirty years, and in none have metastases or recurrence been noted. All eight cases were observed through operative procedure, and there seem to be no records of such tumors discovered at autopsy. Subjective symptoms in these cases have been vague, such as headache, local pain, and tenderness. The tumor is quite fixed, because of its relation to the carotids, and for the same reason it frequently transmits pulsation which has led to a diagnosis of aneurism. In the other cases tuberculous cervical glands and thyroid tumor have been suspected.

Operation usually involves ligation of the carotid, which in one case led to death subsequently through the ligature cutting through the artery. In another case death resulted from broncho-pneumonia, which probably developed because of section of the vagus. The other six recovered completely, and seem to have remained well thereafter. In the two cases that were fatal, autopsy revealed no metastases whatever.

The malignant tumors of the carotid gland testify to its origin in the perithelium, for they form quite typical peritheliomas. The tumor is generally highly vascular, and about the capillaries are layers of epithelioid cells, with a strongly staining oval nucleus, and considerable finely granular cytoplasm. The thickness of these walls seems limited by distance from blood supply, and the perithelial cells tend to form cords with central spaces lined solely by the tumor cells. The lobular structure of the gland is retained, as well as its richness in vessels and nerves.

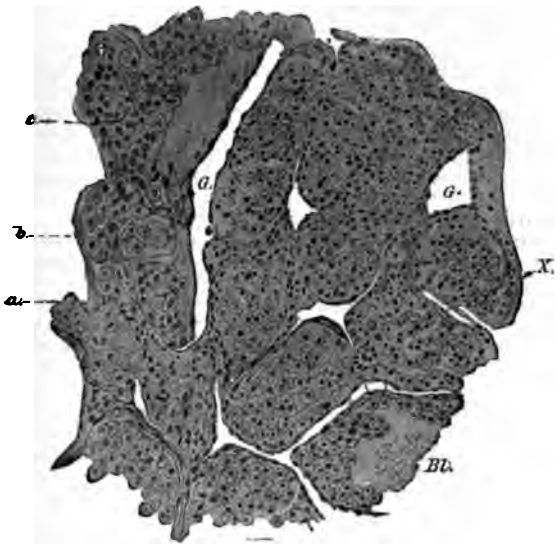

FIG. 5123.—Perithelial Tumor of the Carotid Gland. (After Paltauf.) *G*, Vessels; *Bl*, blood extravasation; *a*, hyaline degeneration of cells; *b*, hyaline degeneration; *c*, hyaline masses.

Usually the tumor lies in the crotch of the carotid, "like a meal sack." The largest tumor reported is that of von Heinleth, which measured 3.5 × 5 × 8 cm., and was 21 cm. in circumference.* *H. Gideon Wells.*

CHYLOTHORAX.—This is a condition in which the pleural cavity contains chyle, due to a break in the continuity of the wall of the thoracic duct or its branches, or to some pathological condition of their walls whereby the contents may be transuded into the pleural cavity. Other writers give the name chyliform to those fluid exudates, in the pleural cavity, which contain fat in smaller amount than is found in the cases belonging to the class first mentioned. Furthermore, as these so-called chyliform fluids accompany tumors of the pleura in many cases, these writers believe that the fat comes from a fatty degeneration of the tumor cells. In a third class of cases the fat of the pleural fluid is supposed to result from lipæmia. In the latter cases the amount of fat contained in the fluid in the pleural cavity is small. Nevertheless, in many cases it may be difficult to differentiate these fluids from true chyle containing a small amount of fat and resulting from some definite lesion of the thoracic duct.

As stated, true chylothorax results from some definite lesion of the thoracic duct or its branches; but since lesions of this organ are not common, and since all lesions of the duct are not followed by chylothorax, the presence of chyle in the pleural cavity is an unusual condition.

Many of the older writers confused chylothorax with empyema or with the fibrinous exudates accompanying certain cases of pleuritis, and consequently some of the cases reported by these men, when studied carefully now, are found to be of a nature different from true chylothorax. It being assumed that this statement is correct, it appears that only forty-seven cases of genuine chylothorax have been reported, besides about fifteen others which are doubtful cases.

ETIOLOGY.—In the undoubted cases the age varied from 2 to 62. Two cases occurred in patients under 10 years of age; 8 in patients from 11 to 20; 7 from 31 to 40; 8 from 41 to 50; 3 from 51 to 60, and 2 after 60. From this it can be seen that the greatest number of cases occur between the ages of 11 and 51. This is explained by the fact that individuals between these ages are more exposed to injuries, or are more subject to new growths—conditions which are frequent causes of chylothorax.

In 41 of the undoubted cases in which the sex was given, 31 were males and 10 were females.

Chylothorax may result from obstruction to the flow of chyle through the thoracic duct, due to pressure from without by new growths or by tuberculous lymph nodes in the mediastinum. The obstruction may also be due to occlusion of the lumen by secondary new growths or to the presence of thrombi in the duct or in the left subclavian vein—in the latter case obstructing the mouth of the duct. Finally, it may be due to the presence of filaria. In other cases chylothorax results from pathological changes in the duct wall or from traumatic injuries to its walls.

Of the undoubted cases 16 resulted from injury to the chest; 9 from pressure exerted upon the duct by new growths outside the duct or by tuberculous lymph nodes; 9 from secondary growths in the duct; 4 from thrombosis of the left subclavian vein; 2 from proliferating lymphangitis; 2 from aneurism-like dilatations of the duct, and 1 each from the following: thrombosis of the duct, operation for removal of carcinomatous lymph nodes of the neck, obstruction to the radicles of the duct from inflammatory thickenings in the mesentery, mitral disease, and filaria. All of these causes either produce a break in the continuity of the endothelial lining of the duct or put the endothelial cells under such abnormal conditions that their nutrition is impaired, and consequently they allow the transudation of the chyle.

SYMPTOMATOLOGY.—The symptoms of chylothorax which result directly from this condition are not characteristic. For the most part they resemble those of hydrothorax or a pleuritic effusion. In most cases the chief, and sometimes the only, symptom is a gradually increasing dyspnœa. In fatal cases this may be accompanied by a rapidly progressing emaciation, although the patient may have a good appetite and may eat well. A few of the patients complain of pain in the affected side if the chylothorax is unilateral, and of a general, indefinite, dull pain in the chest if the condition is bilateral. On inspection lagging of the affected side will be noticed and the intercostal spaces will be more or less obliterated. If the quantity of fluid is large, the heart may be displaced away from the fluid. Palpation reveals a lessened or entirely absent vocal fremitus, depending upon the amount of fluid present. Percussion always gives a dull note on the affected side of the chest, both laterally and behind, the line of dulness being higher in front and lower in the back when the patient sits up, and reversed when the patient lies down.

---

* Since this article was written there has appeared still another report of a tumor of the carotid gland by Reclus and Chevassu, (Revue de Chirurgie, 1903, xxiii., Nos. 8 and 9). This article also includes a full review of the subject to date, with particular reference to operative intervention, which these writers consider, is not indicated unless the tumor is causing much disturbance, since it is probably not malignant and resection involves injury to such important structures.

In seventeen of the forty-seven cases chylothorax was accompanied by chylous ascites, and in one instance by chylopericardium. In one case there was chyluria, and in another milky diarrhœa.

The symptoms referable to other organs are usually due to the same pathological alterations as those which have brought about the chylothorax. In cases of external injury to the duct very few symptoms other than those mentioned appear.

Diagnosis.—The only evidence upon which a positive diagnosis of chylothorax can be based is that afforded by an examination of the fluid. This fluid, as withdrawn by an aspirator, is usually semitranslucent, milky, and opalescent. Its specific gravity is 1.020 in most cases. If allowed to stand, the fluid separates into two layers, an upper, slightly more yellow in color, and resembling cream in consistence, and a lower one, watery in character. If the whole is well shaken and extracted with ether or treated with sodium or potassium hydrate, the fluid becomes clear and loses its milkiness. Chemical examination of the fluid shows that from ninety to ninety-nine per cent. is water. Of the solids, the fat varies from 0.02 to 0.92 per cent.; salts and albumins, and sometimes a small amount of sugar, forming the remainder

Prognosis.—In many cases the prognosis of chylothorax is good. In those which are due to obstruction, the anastomoses of the thoracic duct may do compensatory work, and thus the condition may be relieved. In cases due to injury to the duct from external causes, proper treatment frequently brings about a cure.

Treatment.—For those cases in which the chylothorax is due to some chronic obstruction, aspiration of the fluid, accompanied by rest and nourishing food, is about all that can be done. Cases due to injuries of the chest are treated in a similar manner.

In cases due to injury inflicted during an operation for the removal of carcinomatous or tuberculous lymph nodes in the neck, the duct may be ligated, resected, or packed, all of which procedures have been used.

Frederick A Baldwin

Most of the literature of chylothorax is given by Bargebuhr, Deutsches Archiv für klinische Medicin, 1895, liv., 410, and by Shaw, Journal of Pathology and Bacteriology, 1900, vi., 339.

DISSOCIATION, DIFFUSION AND ACTION OF SALTS.—The advance of physical chemistry in the last fifteen years has thrown a new light upon the behavior of salts in the tissues, and promises to form the basis of the explanation of their presence in all forms of living matter, as well as of much of their therapeutic value. The chief phenomena bearing on biology and medicine are the dissociation of salts and their relation to diffusion and osmosis, and before the results of the application of physical-chemical methods to the biological sciences can be appreciated some knowledge of the recent advances in the theory of these phenomena is requisite.

Dissociation, Ions.—It was formerly held that common salt dissolved in water remained in the same form as that which is familiar in the dry state, the only difference being that crystals divided into molecules. It is now recognized, however, that not only are the molecules isolated from each other, but that a certain number of molecules undergo still further division. The products of this molecular division are known as *ions*, and in the case of common salt are Na ions and Cl ions. The amount of dissociation that occurs varies with the strength of the solution; the weaker the solution the greater the percentage of salt undergoing dissociation. In a one-per-cent. solution of sodium chloride only about one-fifth of the salt is present in the form of molecules, the rest having dissociated into the two ions. These ions are not to be confused with atoms, for although sodium and chloride ions are present, the solution of course possesses none of the properties of metallic sodium or of free chlorine. The ions differ from the atoms in carrying a charge of electricity, the charge of the sodium ion being positive, while that of the chloride ion is negative.

If a battery be connected with the solution the sodium ions hurry to the negative pole or cathode, while the chloride ions give up their charge at the positive or anode. The sodium ion is therefore known as the *cation*, the chloride as the *anion*. At the moment at which the charge of an ion is given up the ion changes to an atom, but it immediately forms fresh combinations with the water, in the present instance NaOH and HCl.

Other salts undergo a similar dissociation in solution in water; KBr forms K and Br ions; $NaNO_3$, Na and NO_3 ions, K_2SO_4 divides into three ions, two potassium and one SO_4; ammonium oxalate forms two NH_4 ions and one oxalate anion, and so forth. The dissociation of acids and alkalies is of great importance, but resembles exactly that of the other salts, acids forming hydrogen cations and the rest of the molecule forming the anion, while alkalies divide into a hydroxyl anion and a metallic cation; HCl thus becomes hydrogen and chloride ions; NaHO, sodium and hydroxyl (HO) ions.

The ions in a solution are in constant motion, and the anions and cations of a substance in solution lose the connection which they possess in the solid state Thus, when potassium bromide and sodium chloride are dissolved together in a sufficient amount of water, it is no longer correct to designate the result as a solution of potassium bromide and sodium chloride, for the potassium ions are in no closer connection with the bromide than with the chloride ions. The bodies present are really the potassium and sodium cations and the bromide and chloride anions In the blood serum, for example, the phosphate ions present are not combined with the potassium nor the chloride with the sodium, but all four are independent, and it is incorrect to speak of the potassium phosphate of the blood serum. When a dilute solution of sodium hydrate is swallowed it is neutralized by the gastric juice, and the reaction is often stated as the formation of sodium chloride and water. In reality the hydrate solution contains sodium and hydroxyl ions, the gastric juice hydrogen and chloride ions, and the resultant fluid contains sodium and chloride ions. The change consists in the disappearance of the hydrogen and hydroxyl ions which have formed water, the chloride and sodium ions having been present to begin with and remaining unchanged

Dissociation occurs in salts, including under this term acids and alkalies, but it is not developed equally in all salts. Those acids and bases which are generally considered to be the "stronger" dissociate more readily than the weaker combinations, and the monovalent salts more readily than the bivalent The inorganic salts dissociate more readily than the organic, and the same holds true for the bases. All of those bodies in solution serve as electrical conductors; in fact, the passage of electricity through watery solutions is only possible through the presence of ions, and the conductivity of solutions is thus a measure of the degree of dissociation. Those substances which are dissociable are therefore known as electrolytes. On the other hand, many organic substances are incapable of conducting electricity and are also incapable of dissociation. Thus alcohol contains an hydroxyl (— OH) in combination with ethyl (C_2H_5), as sodium hydrate contains an hydroxyl in combination with sodium. Alcohol is, however, incapable of forming ions, and therefore is a non-electrolyte in aqueous solution, while sodium hydrate dissociates readily into hydroxyl and sodium ions, and these are capable of conveying an electric current.

Sodium hydrate has a characteristic action in the tissues, causing corrosion. This might be due to either the sodium or the hydroxyl ion. As a matter of fact, however, the sodium ion is present in many solutions which are devoid of corrosive effects, for example, in solutions of sodium chloride The conclusion, therefore, is that the hydroxyl ion is the corrosive in this case. Alcohol has no such corrosive action as sodium hydrate, and this corresponds with the fact that alcohol is not an electrolyte, *i.e.*, does not liberate the hydroxyl ion, although it contains hydroxyl. Many other similar examples might be cited, all going to show that in many instances the therapeutic effects of a body are due, not to the molecule administered, but to the ions into which it dissociates in the fluids of the body. In fact in administering an electrolyte, the physician gives not one but two or more substances, which may each effect changes in the organism. As a general rule in therapeutics one ion is so powerful that the other may be neglected: for example, in morphine sulphate the alkaloidal cation is so active that the sulphate ion may be ignored, and the sulphate has therefore the same effect as the hydrochlorate of morphine. When the two ions are more equal in pharmacological activity, however, each has to be taken into consideration; for example, magnesium sulphate dissociates into magnesium and sulphate ions, each of which has a retarding influence on absorption in the bowel, while magnesium chloride similarly forms magnesium and chloride ions, of which the latter is indifferent in the bowel. The sulphate of magnesium has thus a more powerful purgative action than the chloride, and is also more active than sodium sulphate, which forms the purgative sulphate and the indifferent sodium ions.

Another example of the importance of ions to the understanding of therapeutic action and to its successful practice is offered by the bromides. Potassium and sodium bromides have a depressant action on the central nervous system, and as this is absent in the case of the chlorides of these metals, it is obviously due to the bromide ion. Bromated camphor also contains bromine in chemical combination, and attempts have been made to substitute it for the bromides as a depressant. But bromated camphor does not dissociate and no bromide ions are formed, so that whatever properties it may possess, it cannot be compared with the bromides of potassium or sodium.

The action of salts depending on the ions, the intensity naturally varies with the rate of dissociation. This is well exemplified in the local effects of the heavy metals: such salts as the chlorides and nitrates, which dissociate readily, are much more active locally than the sulphates and organic salts which divide into ions less rapidly, provided, of course, that all are equally soluble and have no special characteristics, such as deliquescence. The newer views as to the dissociation of salts and the important rôle of the ions explain why such bodies as the ferrocyanides have the effects neither of iron nor of cyanides, for neither iron nor cyanide ions are formed from them in solution. Similarly the cacodylates differ from arsenous salts because they do not liberate the arsenous ion except after decomposition in the body. Now in the case of potassium arsenite, the arsenite ion is the active constituent, and the cacodylates can possess this only when they are broken down in the tissues into arsenous salts. The slowly dissociating salts are thus often used to avoid the local action of the more irritant metals; for example, many of the recent compounds of iron have the advantage over the older salts of causing less local irritation, while they have practically the same effect on the blood formation Similarly several new preparations of mercury have been introduced with the view of lessening the local action on the stomach and bowel, or of lessening the irritation induced by the hypodermic injection of mercury. These compounds, when soluble, are more slowly dissociated than corrosive sublimate, and, there being fewer mercury ions present at any one time, the local irritant action is accordingly reduced.

The disinfectant action of the heavy metals also depends largely upon ionization, for the destruction of the germs is due to a chemical reaction between the metal and the protoplasm of the microbes; and the larger the number of free ions the greater the tendency to union. The attempt has been made to obtain germicides devoid of the local irritant action by forming less readily dissociating salts than those in ordinary use. A large number of preparations have thus been introduced, partly compounds with organic acids, partly with proteid bodies. But as the irritant and the germicidal action of most metallic compounds depend on the same factor, namely, the free ions, it seems likely that the lesser degree of irritation induced by these is obtained only by the sacrifice of much of the disinfectant value.

The double salts are much less readily dissociated than the simple, and not infrequently appear to liberate somewhat complicated ions, as in the case of the ferrocyanides noted above. They are therefore largely devoid of the local action of the parent substances, and this may be taken advantage of in therapeutics occasionally.

When two salts which have one ion in common are dissolved together in water, the dissociation is considerably reduced. For example, if corrosive sublimate be dissolved along with sodium chloride, the former is less dissociated than if it were dissolved alone in the same amount of water. In accordance with this general rule, it is found that the addition of sodium chloride to a mercuric perchloride solution lessens both its irritant and its germicidal power, and in cases in which it is desirable to mitigate the former, and in which the latter is of no importance, as in the treatment of syphilis by the hypodermic method, this mixture may be used instead of the pure mercuric salt.

The complete treatment of the dissociation of salts would involve a large part of pharmacology and therapeutics, in which the importance of the phenomenon is daily becoming more evident. The inorganic materia medica is more dependent on the principle than the organic, as the dissociation is much more complete in the former. It is possible to exaggerate the importance of the new law, however, for many of the facts and principles of therapeutics remain unaltered by its introduction. For example, it is undoubtedly more in accord with modern theory to attribute the effects in epilepsy to the bromide ion than to the bromides, as was formerly done, but this is after all a matter of nomenclature, and it is perhaps necessary at the present time to remember that there was a science and practice of therapeutics before the ion theory was broached. On the other hand, there can be no question that it has thrown much light on many questions, and removed many misconceptions. In the case of the bromides, for example, it is scarcely possible to maintain at the present time that the bromide of ammonium is superior to that of sodium, except possibly in regard to the local action on the alimentary tract, for in each case the active constituent is the bromide ion, and this is equally readily furnished by either salt.

In physiology and biology generally the theory of ions is of great importance, as is at once apparent from the fact that the fluids and tissues of the body can only conduct the electric current through the presence of ions. Every electric stimulus causes a change in their distribution, and every electrical discharge (and electrical changes accompany every movement and every other form of activity) is intimately connected with the presence of free ions, and in fact is possible only in their presence. The whole of electro-physiology, and naturally of electro-therapeutics, has thus to be based on the ionic theory, and the fact that every life process so far investigated has proved to be accompanied by electric changes indicates that the presence of free ions is necessary to life itself. This of course agrees with the fact that inorganic salts are present in every living tissue.

Not only do living tissues require the presence of free ions, but even dead colloid material is altered very remarkably by them. And certain facts have recently been brought out in regard to the dependence of the proteids on certain ions which promise to have a far-reaching influence on biology and hence on medical science. It has long been known that many proteids, notably the globulins, are precipitated from solution when such salts as the sulphates of magnesium or ammonium are added to them. But Hardy has recently shown that the precipitation and solution of colloids, such as the proteids, depend largely on the valency of the ions present in the solution. Thus bivalent cations precipitate some colloids in comparatively small quantities, and trivalent cations are still more efficacious, while monovalent cations tend to keep them in solution or have a very much smaller precipitating action. The bivalent and still more the trivalent cations thus tend to oppose the monovalent cations in regard to colloid solubility; and as ions are necessary to the life phenomena, the monovalent must be counterbalanced by the bivalent in the tissues, for either of these alone would tend to change the colloids from the normal condition to one of excessive or deficient fluidity.

A good deal of interest has been aroused in regard to the antagonistic action of ions in living tissues, which is found to present some similarity to that described by Hardy in dead colloid matter. The organ examined with most care in this relation is the frog's heart, a very sensitive reagent to changes in its environment. It has long been known that the excised frog's heart will beat for a long time when supplied with oxygenated blood or serum, and also in fluids containing no organic matter, but merely the inorganic salts of serum. On the other hand, solutions of non-electrolytes, such as sugar, fail to maintain the contractions. The presence of ions in the perfusing fluid is therefore necessary to maintain the heart in activity. But all ions are not equally efficient, for a certain amount of sodium chloride is found to maintain the contractions longer than any other single salt. The contractions very soon become weaker in sodium chloride solution, however, and finally the heart is arrested. But this arrest may be prevented if the solution contain in addition to sodium chloride a trace of a calcium salt; on the other hand, a heart which has ceased to beat in sodium chloride solution may be induced to resume its pulsations if calcium be added to the perfusing solution. This phenomenon was first noted by Ringer,* and has been confirmed by all subsequent observers; but views differ as to the interpretation to be given it. Howell has upheld the theory that sodium and calcium are both necessary to the heart, and that when sodium chloride solution is perfused alone, the calcium in the heart muscle diffuses out and is washed away and the heart ceases from its losing one of the necessary constituents, calcium. In support of this view he has shown that when the lime ions are removed by other means, *e.g.*, by precipitating them with oxalates, the heart ceases to beat.

Loeb, on the other hand, holds that the heart can only beat in solutions of electrolytes, and that the least poisonous of these is formed by sodium and chloride ions. Even these are not altogether harmless, however, and after a time the heart ceases from poisoning with the sodium ion. Calcium ions are antagonistic to sodium, and the addition of lime salts therefore reinstates the contractions. To put it shortly, the heart ceases in sodium chloride solution because, according to one view, a necessary constituent, calcium, is all washed out, according to the other, because the sodium is poisonous and has to be antagonized by the lime. Loeb's view appears, at first sight, the less plausible of the two, because it has been held that sodium chloride is a perfectly indifferent substance to animal tissues. It must, however, be remembered that here there is always sufficient calcium present to neutralize any poisonous action of the sodium, and this argument has therefore little weight. On the other hand, he has brought forward some very telling facts in its favor in his investigations of other organs than the heart. Without going into all of these, it may be mentioned that he found striated muscle undergo irregular twitching contractions in sodium chloride solution, but these were arrested by calcium and other bivalent salts, so that the phenomenon is not confined to the heart muscle. Loeb found a small fish, fundulus, which lives in sea water or in distilled water indifferently, but dies in a solution of sodium chloride of the same density as sea water. This can only be interpreted as indicating that there is something present in sea water which prevents the poisonous action of sodium chloride. On investigating the subject further he found that in a solution of sodium chloride, to which traces of calcium salts were added, the fundulus and its eggs lived as well as in sea water. The conclusion is inevitable that the lime normally present in sea water antagonizes the poisonous action of sodium chloride in this case. The parallel between the behavior of this animal and that of the frog's heart and other organs is so close as to form an important support for Loeb's theory of the interaction of the ions. It may be added that numerous examples of a similar antagonism are already known in more complicated ions than sodium and calcium. Thus the antagonism of atropine and pilocarpine, of curarine and physostigmine in striated muscles, and of the central nervous depressants and strychnine is similar, although these differ in not being essential to the function of the organs on which they act.

It is to be noted that in the case of fundulus, the action of sodium chloride is antagonized by a comparatively minute amount of calcium, and also by corresponding small quantities of other bivalent and trivalent ions, such as those of barium, strontium, lead, zinc, chromium, and alum. Similarly calcium removes or lessens the poisonous effects of potassium salts on the heart, and the potassium ion is also necessary to the normal contraction, so that the antagonism is believed by some observers to be related to the valency of the metallic ion. The fact that electrolytes are necessary to the heart and other organs suggested to Loeb and Mathews the view that the antagonism is due, at any rate in part, to the electric charge carried by the ions, but this is very far from being proved or from being generally accepted. For it has been found that striated muscle, which undergoes abnormal contractions in solutions of several monovalent salts, fails to do so in all; and while the contractions are arrested by some bivalent metals, others have not this effect. The conclusion seems justified that the antagonistic effects are not immediately associated with the valency or the electric charge, but are the results of some unknown special relation between the ions and the protoplasm, these relations differing in different organs and for different metals. In other words, the calcium-sodium antagonism appears to be of the same nature as the atropine-pilocarpine one, and is equally inexplicable in the present stage of knowledge.

While each of the cations alone is poisonous and has to be antagonized by some other cation, ions are necessary to the life processes. Protoplasm can exist then only in the presence of a number of different salts, of which the chief liberate sodium, chloride, calcium, and potassium ions. The poisonous effects of sodium are counteracted by very small quantities of calcium, the ratio obtaining between those in the best media being about 1,000 to 1.

An electric current can be conducted through a watery solution only by means of the ions at liberty in it. The extent of dissociation in the fluid may therefore be estimated by the conductivity of the solution or inversely by the resistance met by the current. As long as there is only one salt in solution the calculation is simple and the results are unequivocal. And however many bodies are in solution, the amount of dissociation may be estimated, although if large amounts of undissociable matter (non-electrolytes) be present the results are too low. But such estimations give no clew to the nature or relative amounts of the salts in solution. Some efforts have been made to apply this method to the examination of the urine and the blood in the hope that light might be thrown on the condition of the kidney by its means. As a matter of fact, however, the urine is much too complex in its composition to permit of results of much value being obtained. The chief electrolytes here are the chlorides, and a small variation in their percentage may induce a large deviation in the resistance, while if the chlorides vary in one direction and the other salts in the opposite, the resistance may remain almost unchanged in spite of great alterations in the composition of the urine. The chief non-electrolyte is the urea, and its presence in large amount may increase the resistance without any marked change in the amount of salts or their dissociation having occurred. The method cannot therefore be regarded as replacing the chemical analysis of the urine, for its results are of a totally different kind. And it has not been shown by observation that the results obtained by measuring the electrical resistance can be utilized for diagnosis or to indicate the value of therapeutic measures.

---

* Ringer's solution, which has been widely used in physiology as that most suitable for conserving the life of tissues, contains sodium, potassium, calcium, chloride, phosphate and carbonate ions and is made up of 100 c.c. of 0.75-per-cent. $NaCl$, 5 c.c. of 0.25-per-cent. $CaCl_2$, 2.5 c.c. of 0.5-per-cent. $NaHCO_3$ and 0.75 c.c. one-per-cent. KCl.

Diffusion and Osmotic Pressure.—When distilled water is carefully poured upon a solution of sugar so that the two liquids do not immediately mix, the sugar molecules soon begin to penetrate into the pure water, and after a sufficient lapse of time the contents of the vessel become homogeneous, the percentage of sugar in what was distilled water being the same as in the part corresponding to the original solution. The explanation is that the molecules are in constant movement and, diffusing in all directions, some of them penetrate into the pure water, and this process goes on until the latter contains as many particles as the original. The movement still continues, but now as many molecules diffuse back into the lower layer as into the upper so that equilibrium is maintained. The process is the same as that seen when a crystal of sugar is dissolved, for here also the constituent molecules leave each other and wander throughout the fluid.

When a membrane is stretched between the two fluids, the result varies with its character. If the membrane offers no resistance to the passage of water and sugar, the same phenomenon is observed as if they were not separated by a membrane; the fluid on each side becomes homogeneous, although this generally takes more time, owing to the fact that currents are less liable to aid the process. If the membrane be permeable to neither sugar nor water, of course the fluids remain completely isolated and unchanged. On the other hand, some membranes, known as semipermeable membranes, permit the passage of water and not of sugar. For the sake of clearness, suppose that a solution of sugar be placed in the upper vessel of a diffusion apparatus with a semipermeable membrane, and distilled water in the lower. In this case the molecules of water in the lower vessel can penetrate into the upper, while on the other hand those in the upper cannot escape into the lower. The reason for this is simple; for if water escaped from the sugar solution without an equivalent amount of the sugar, the solution would be more concentrated. Now in order to concentrate the sugar solution, work has to be done; for example, it may be concentrated by heating it. But in the diffusion apparatus there is no source of energy available for concentration, and the result is that the water cannot escape from the upper vessel. On the other hand, the membrane being permeable for water, the molecules in the lower vessel find no difficulty in entering the upper. The result is that the sugar solution becomes more dilute, while the water in the lower vessel diminishes in volume until it may disappear altogether. If sufficient pressure be applied to the sugar solution, the water will cease to enter it from the lower, and the amount of pressure which suffices to arrest the movement of the water is known as the *osmotic pressure* or *osmotic tension* of the sugar solution. The phenomenon is known as osmosis, but it must be recognized that osmosis is merely a diffusion under special circumstances, for the whole is due to the movement of molecules, all of which are free in ordinary diffusion, while some of them (*e.g.*, sugar in the above example) are restricted in their movements in osmosis.

The osmotic pressure is found to vary directly with the number of molecules in the solution, a concentrated solution causing a more rapid flow and a higher pressure than a more dilute one. Thus a one-per-cent. solution of cane sugar exercises a pressure of 585 mm. of mercury, a two-per-cent. of 1,070 mm., and so on. The pressure exercised by even dilute solutions is very considerable, as is seen on transforming these figures into atmospheres, for a two-per-cent. sugar solution is then found to give a pressure of nearly one and a half atmospheres. This is even more remarkable when a smaller molecule than sugar is chosen. Thus a one-per-cent. solution of potassium nitrate exercises a pressure of over three atmospheres. As the pressure depends upon the concentration of the solution, it decreases and the movement becomes slower as the process goes on, for the water diffusing into the sugar solution dilutes it.

As osmosis is merely a special form of diffusion, it follows that only diffusible and dissolved substances can exercise osmotic pressure. The colloids, such as proteids, are therefore generally believed not to have any influence on the movement of fluids because they are not in true solution, but rather in a state of suspension. Others hold that though in solution, they exercise no appreciable tension because the molecule is so large. As each molecule in solution has the same osmotic effect, it stands to reason that a one-per-cent. solution of sugar must induce an immensely greater pressure than a one-per-cent. solution of albumin, because the number of molecules dissolved in the former is so much greater. The proteids always contain a certain amount of soluble salts, and these are sufficient to cause some osmotic tension; so that it is not yet decided which explanation is correct, but in any case the osmotic pressure of the proteids is so small as to be negligible.

Very often membranes are met which offer a certain amount of resistance to the passage of dissolved diffusible bodies while allowing water to pass freely. If such a membrane separated a sugar solution and water, the latter would at first pass through into the solution rapidly under considerable osmotic pressure. But some sugar also passes downward, and there is thus formed a strong solution of sugar above rapidly being diluted and a weak solution of sugar below rapidly becoming stronger from the continued permeation of sugar into it and the escape of water upward. Finally equilibrium is reached by the solutions on each side of the membrane attaining the same concentration.

The same principles hold when solutions are present on each side of the membrane, the direction of flow being always toward that side on which the larger number of molecules are present, provided the membrane is semipermeable. The osmotic pressure is determined by the difference of the osmotic pressures of the two solutions toward distilled water. If the same body is in solution on the two sides of a permeable membrane, the water tends to pass toward the stronger solution, while the solid passes in the opposite direction until equilibrium is reached. When two different bodies in solution, *e.g.*, sugar and urea, are separated by a membrane which is permeable by each of them, they diffuse freely through it and the two solutions soon become identical, each containing the same percentage of urea and sugar. If the urea can penetrate the membrane while the sugar fails to do so, the osmotic pressure is that of the sugar solution and the urea solution will pass toward the sugar as long as the latter can exert appreciable pressure. In other words, no osmotic pressure is exerted by a fluid toward a membrane which it can pass through.

When neither sugar nor urea can pass through the membrane, the water passes from the solution containing the smaller number of molecules toward that containing the larger number until equilibrium is established by each solution containing the same number of molecules per cent. of water. The weaker solution is often known as the *hypotonic* or *hypoisotonic*, the stronger as the *hypertonic* or *hyperisotonic*, while two solutions possessing the same osmotic pressure are known as *isotonic* solutions.

In biology the problems in diffusion are much more complex than the examples given above, but they all depend on these general rules. In the first place the solutions are much more complicated, containing a number of different substances in solution; in the second, the membranes are neither perfectly permeable nor semipermeable. They permit the passage of some of the constituents of the fluids, but as a general rule few of these pass quite freely, and the amount of resistance varies with each kind of molecule. Further it must be recognized that a dissociated salt exercises not the osmotic tension of a molecule, but that of its ions. In a dilute solution of sodium chloride, for example, the osmotic pressure is not measured by the number of molecules, for each ion exercises the same osmotic effect as a molecule of sugar, or as an undissociated molecule of salt.

Each cell in the body may be conceived as the inner vessel of a diffusion apparatus, separated from the surrounding fluids by a membrane, for though this membrane has no anatomical existence, the colloid nature of protoplasm has the same final effect as if the cell were surrounded by a membrane. All cells are permeable by water, but each kind of cell appears to differ in the facility with which it permits the permeation of salts and the other bodies dissolved in the body fluids. Some, for example, allow the passage of ammonium readily, while others refuse it entrance. Others take up sodium sulphate as readily as sodium chloride, while others accept the latter and reject the former. Now if the intercellular fluid contains any substance which is not capable of penetrating the cells, it must exert osmotic pressure on the cell; and unless this pressure is counterbalanced by other bodies in the interior of the cell which similarly cannot escape from it, the fluid of the cell will be drawn out and shrinkage will result. Every cell in the body then must be conceived as existing in a condition of equilibrium, the osmotic tension of the salts, etc., in its interior being pitted against that of the surrounding fluid, and the smallest change in either of these leading to an inflow or outflow of water from the cell. Now such changes are continually in progress, for as the proteids and carbohydrates of the cells are broken down into simpler bodies, soluble in water, each molecule so formed acquires osmotic properties, and either diffuses freely into the surrounding fluid, or causes an inflow of water into the cell. In either case the equilibrium is disturbed until the new product is removed by the excretory functions. The importance of diffusion and osmosis in the functions of the body cannot therefore be overestimated; in fact, it may be said that while the more obvious movements of the fluids of the body are determined by the circulatory mechanism, the finer but no less important exchange between the cells and the intercellular fluid is in large part directed by the laws of diffusion. And while a knowledge of the arterial supply of an organ is recognized to be necessary for an understanding of its physiology and pathology, it is probably no less desirable to ascertain the permeability of its cells for the constituents of the surrounding fluids. The osmotic pressure varying with the nature of the membrane or cell, and also with the salt in solution, the only way to determine the results of exposing the cell to a solution of the salt is the experimental, and a considerable amount of work has been done in this direction, so that the permeability of some cells is known for a large number of salts and other bodies. In this method of procedure the cells under examination, *e.g.*, the red blood cells, are exposed to solutions of different strengths, and the concentration which induces neither shrinking nor swelling of the cell is ascertained. This concentration is that balanced by the intracellular fluid, and the solution is said to be isotonic for that cell. The salt in solution must obviously fail to penetrate the cell, or do so only extremely slowly, for if it permeates freely the water in which it is dissolved will also pass into the cell and expand it. In such an isotonic solution the number of molecules percent is exactly equal to that in the interior of the cell, and a solution containing the same number of molecules and ions of any other non-permeating salt will also be isotonic and cause no change in the size of the cell. For example, if a 0.75-per-cent. solution of sodium chloride has been found isotonic for the blood cells, an equivalent solution of sodium sulphate or of ammonium chloride will also preserve the size of the cells unchanged, provided these salts are equally incapable of permeating the cell. If one of these, *e.g.*, that of ammonium chloride causes swelling of the cell and the escape of hæmoglobin, then this salt must permeate more freely than sodium chloride.

In the case of non-dissociating bodies, such as alcohol, sugar, or urea, equimolecular isotonic solutions can be made by calculating the atomic weights. In the case of the salts this method fails, for the dissociation varies for different salts and for different dilutions, and each ion exercises the osmotic pressure of a molecule. Other methods have therefore been adopted, and of these the estimation of the depression of the freezing point has come into general use in the last few years. This method, it must be emphasized, does not indicate the osmotic pressure for all membranes, nor the permeating qualities of the substance, but only the total number of molecules and ions in the solution. It depends upon the fact that solutions containing the same total number of ions and molecules per cent. freeze at the same temperature, which is lower than that at which distilled water freezes to ice. If two solutions lower the freezing point an equal extent below 0° C., therefore, they contain the same number of ions and molecules, and are isotonic toward a semipermeable membrane. The estimations are made by means of thermometers reading to $\frac{1}{100}$° C., and allowing of approximations to $\frac{1}{1000}$° C., and with some care and practice in the method very exact determinations may be made. A very extensive use of this freezing method has been made in experimental work, and some results have also been obtained in clinical medicine, but the details of the method can only be given in works dealing specially with this subject. The depression of the freezing point of any solution below that of pure water is generally expressed by the symbol Δ. If the salt is not capable of penetrating a cell, its osmotic pressure varies with the Δ of the solution, *i.e.*, with the concentration of molecules and ions, and if two solutions of non-permeating salts have the same Δ, their influence on the movement of the fluid of the cell will be equal. On the other hand, if the salt permeates without difficulty, the Δ is of no significance in regard to the effects of the solution on the cells.

The relations of the salts to the tissues has been worked out in most detail in the case of the red blood cells. It is found that in a 0.75-per-cent. solution of sodium chloride, the cells maintain their form and size unchanged, *i.e.*, the salt fails to penetrate the cells and exercises the same osmotic pressure as the diffusible contents of the cells, or is isotonic with the fluid in the interior of the cell. If the cells be exposed to pure water, they swell up and discharge their hæmoglobin, and the same occurs in weak (hypotonic) solutions of sodium chloride. The salt here being in lower concentration than the contents of the corpuscles, a current of water sets inward toward the stronger solution. In solutions of greater concentration than 0.75 per cent. (hypertonic solutions) the cells shrink from the loss of water, which flows outward toward the stronger solution. Similar phenomena are seen when other salts of the fixed alkalies are employed, so that these salts appear to be unable to penetrate the corpuscles except to a very slight extent.

In solutions of ammonium chloride, on the other hand, the cells swell up and lose their hæmoglobin, whether the solution be isotonic with 0.75-per-cent. NaCl, or much stronger. The conclusion is that the ammonium chloride can penetrate the cells and thus exercises no osmotic resistance to the entrance of water, so that the effect of ammonium chloride solution is practically identical with that of pure water. Many other ammonium salts resemble the chloride in penetrating the red blood corpuscles; but others, such as the sulphate and phosphate, fail to enter the cell entirely, or penetrate with great difficulty. The sulphate and phosphate ions, therefore, like the sodium and potassium ions, are non-permeating, and exercise osmotic pressure on the cell wall. Unless both ions of a salt can enter the cell, neither does so. Many non-electrolytes, such as urea and compound ammonias, appear to enter the blood cells freely.

The absorption of salt solutions in the intestine also presents an interesting example of the importance of diffusion in vital processes. A solution of sodium chloride isotonic with the blood is absorbed readily, whence it is inferred that sodium chloride can penetrate the mucous membrane. A hypotonic solution is similarly taken up easily, and still more readily pure water. A hypertonic solution, on the other hand, disappears from the bowel more slowly, and very often the fluid first increases in the lumen until it has become almost isotonic with the blood, and only then disappears into the tissues. The sodium chloride does not, therefore, permeate the bowel wall without resistance, otherwise a hypertonic solution would be taken up as quickly as distilled water. On the contrary, a hypertonic solution first exercises osmotic pressure on the cells and causes them to lose water. At the same time some of the chloride has disappeared into the cells, and the solution remaining is diluted with the water exuding, until it is so weak that the osmotic resistance is overcome by the absorbing forces and the whole is absorbed into the blood.

When the sulphate of sodium passes into the bowel in solution, this feature is still more marked. An isotonic solution has little tendency to be absorbed, and on the other hand is not increased in volume, the solution in the bowel counterbalancing the osmotic pressure of the cell contents. A hypotonic solution decreases slowly because its osmotic pressure is less than that of the cell contents, and water therefore tends to pass from the weaker fluid in the lumen to the stronger in the blood; but the fluid escapes from the bowel much more slowly than in the case of an hypotonic solution of sodium chloride. If hypertonic solutions be used, the bulk is at first much increased owing to fluid from the blood escaping into the stronger solution. Finally the sulphate solution becomes isotonic with the blood and is very slowly absorbed if the weight of the fluid in the bowel does not set up reflex peristalsis and cause evacuation. This slow absorption from the bowel is still more marked in the case of magnesium sulphate, in which both ions appear to be taken up with reluctance by the mucous membrane. As these salts fail to leave the bowel and retain the water in which they are dissolved, they render the contents more fluid than usual, and the unusual weight and distention cause peristaltic movements and evacuation. The purgative action of the saline cathartics arises from the difficulty with which they enter the epithelial cells. It is to be remarked that here, as in the case of the red blood cells, the sulphates diffuse with greater difficulty than the chlorides; on the other hand, the chlorides of the fixed alkalies are taken up freely by the bowel wall, while they fail to permeate into the corpuscles, and the oxalate of ammonium, which penetrates the blood cells, is rejected by the epithelium.

The presence of the salt solution in the stomach and intestine inducing such movements of fluid into the bowel and back into the blood, naturally causes considerable disturbance in the distribution of the fluids of the body. When a strong sulphate solution is diluted by fluid poured into the intestine, for example, this fluid comes from the blood and indirectly from the fluids of the tissues. A similar exchange without doubt follows the absorption of salt solutions into the blood, but this is difficult to follow experimentally. When salt solutions are injected into the blood-vessels, however, it is found that there is a marked disturbance of the equilibrium of the tissues. If the solution is hypertonic, there is a flow from the lymph spaces toward the blood which continues until the plasma recovers its normal density. The current then is found flowing in the opposite direction from the blood-vessels into the tissues. The lymph measured in the thoracic duct is found to be lessened at first owing to the inflow into the vessels, but later more lymph passes along the duct than usual, owing to the current of fluid passing toward the tissues from the blood.

The injection of salts into the blood-vessels or their absorption from the bowel leads to considerable diuresis. The explanation of this diuresis is still a matter of discussion, but there can be no question that the diffusion and osmotic properties of the salts play an important rôle in this result. The accumulation of fluid in the blood at the expense of the tissues naturally leads to an unusual bulk of the contents of the blood-vessels, and this in turn to an increased pressure in the capillaries. This engorgement of the vessels cannot be relieved by an outflow into the tissues, for this is prevented by the current of lymph pouring into the vessels. Only one way of escape remains, that through the kidneys, and the inflow of lymph is therefore accompanied and followed by diuresis, which is thus in large part explained by the physical forces, although there is doubtless much still obscure in the process. Different salts vary in their diuretic properties, and this might at first seem to indicate that the diffusion was of secondary importance. As a matter of fact, however, many of these differences can be explained by varying rates of diffusion. For example, the sulphates are as a general rule inferior diuretics when given per os, because they fail to reach the blood for the most part from their cathartic action. On the other hand, sulphate of sodium, injected intravenously, causes much greater diuresis than an equimolecular solution of sodium chloride, even if it causes the same inflow into the vessels and the same degree of hydræmia. This has been explained, however, by the renal tubules failing to absorb the sulphate, while taking up the chloride readily. If this is the case, as appears very probable, the sulphate failing to penetrate the renal tubules and thus return to the blood, must hold a certain amount of water in the tubules which would otherwise return to the blood. The chloride, on the other hand, returns readily through the epithelium lining the tubules, and thus retains less water in the tubules and causes less diuresis. In this view the epithelium of the tubules resembles that of the intestine in repelling sulphates and phosphates and admitting chlorides readily, but differs from it in showing little avidity for urea and sugar.

The urine is generally a much more concentrated fluid than the blood; that is, it contains a larger number of molecules and ions. The kidney must thus do a considerable amount of work in concentrating such a fluid from the more dilute blood plasma, and by estimating the △ of the blood, which is remarkably constant (about − 0.56° C.), and comparing it with that of the urine, the actual work done may be estimated exactly. Dreser calculated the work done by the kidney in forming 200 c.c. of average urine at the large sum of 37 metre kilograms, or over 270 foot-pounds, but this may be greatly exceeded in cases of very concentrated urine. Attempts have been made to use this method of estimating the work of the kidney in clinical medicine, and the subject has been treated of at great length in recent years under the title of cryoscopy. As yet no results of importance bearing on diagnosis or prognosis in renal affections have been arrived at.

When very concentrated solutions of salts or other diffusible bodies are brought in contact with living cells, some fluid escapes from these into the solutions, and this often deranges the activity of the cell. This may be observed in the stomach when strong solutions of such harmless bodies as common salt or sugar are swallowed, the disturbance of the equilibrium manifesting itself in irritation, nausea, and vomiting. In the same way a strong solution applied to wounds or mucous membranes causes irritation and pain from the withdrawal of fluid and precipitation of proteids. The same desiccation of the tissues may arise to a less degree from the presence of excess of salt or sugar in the blood. The organs which suffer chiefly are the brain and spinal cord, as is manifested in tremors and convulsions, and later by paralysis and asphyxia, when strong solutions of salts, sugar, urea, or other diffusible substances are injected intravenously in animals. *Arthur R. Cushny.*

DWARFISM.—Nanosomia or microsomia is a condition, found in both animals and plants, in which the stature and weight fail to reach the normal minimum for individuals of the same species. The word *nanosomia* is derived from two Greek words, *νᾶνος*, a dwarf, and *σῶμα*, a body, the former being the equivalent of the Latin *nanus* or *pumilio*, the Anglo-Saxon *dweorg* or *dwerg* and the German *Zwerg*.

From stray references to the subject in the pages of writers of antiquity, we may infer that a belief in the existence of dwarfs has been general from the most remote times. Homer, Herodotus, and Aristotle, among others, speak of a pigmy race that was to be found near the sources of the Nile. In India, too, there was a current belief in dwarfs descended from Hoonuman, the monkey-god. Many of the statements in regard to dwarfs are, however, so wildly improbable that they were, no doubt, based on mere "sailors' yarns," and are entitled to about the same amount of credence as the famous "Travels" of Sir John Mandeville. That they contain a modicum of truth, nevertheless, is proved by the discovery of diminutive peoples by modern explorers, such as Paul Du Chaillu, Schweinfurth, Battel, and Kolle. Dr. Schweinfurth, for instance, has found in the country to the south of the Nyam-Nyam a race called the Akkas, varying in height from four feet to nearly five, who are probably the same as those referred to by Herodotus. Any exhaustive discussion of the subject of dwarfism from an ethnological point of view would be out of place in a work of this nature, which is more properly concerned with the biological and pathological problems involved, but yet, apart from the interest that always invests the curious, it may not be entirely stale, flat, and unprofitable to possess ourselves of the main facts.

From the golden days of imperial Rome it was the fashionable thing to keep dwarfs. The most famous of these were Conopas and Andromeda, belonging to Julia, the niece of Augustus, each of whom measured only two feet four inches. Many of these dwarfs were, no doubt, the natural article, but the number of these was insufficient to supply the demands of cruel display and luxury; consequently they had to be produced by artificial means. One favorite method was the simple one of depriving children of suitable food. They became rickety, and while many died, those who survived were highly prized. Another plan, in some vogue, was to rub the back with the fat of bats, moles, or dormice. Somewhat similar was the practice of washing the backs and feet of pups, the drying and hardening of the parts resulting from this being supposed to stunt the growth. Even at the present time, it may be remarked, attempts are made to limit the growth of boys intended for jockeys by sweating. The practice of keeping dwarfs persisted through the Middle Ages into the eighteenth century. Lady Mary Wortley Montagu, when in Germany, found the dwarf a necessary appanage of every noble family. She describes the imperial dwarfs at Vienna "as ugly as devils," and, "bedaubed with diamonds." In these days dwarfs were not infrequently noted for their wit and wisdom, and, like the court jesters, whom in fact they superseded, were allowed unlimited freedom. It is said that one of the Danish kings actually made his dwarf prime minister in order to get at truths that other men were afraid to utter. Peter the Great, among other vagaries, was interested in dwarfs, and in 1710 gave a feast to celebrate the marriage of his favorite Valakoff with the dwarf of the Princess Prescovie Feodorovna, at which seventy-two dwarfs of both sexes were present. The practice of keeping dwarfs was widespread, and has been immortalized in the canvases of some of the most celebrated painters, notably Velasquez, Raphael, Paul Veronese, Domenichino, and Mantegna. Their delineations are in some cases of much value in enabling us to determine the nature of the dwarfism known to former times. In fiction, too, the dwarf has played a prominent part, as readers of "Peveril of the Peak" and "The Black Dwarf" will remember.

Some personages, famous in history, have been of small or even diminutive size. Philetas, of Cos, tutor of Ptolemy Philadelphus, was, according to Ælian, so light as well as small that he was obliged to carry leaden weights in his pockets to prevent his being blown away. Others that might be mentioned are Attila the Scourge, Æsop the fabulist, Procopius, Gregory of Tours, Pepin le Bref, Prince Eugene, Admiral Gravina, Fleury and Garry the actors, Arendt the Danish antiquarian. In England the history of dwarfs is traceable to mythological times. The origin of the almost generic title of "Tom Thumb" is to be found in an ancient ballad, which informs us that "In Arthur's court Tom Thumb did live." The most famous English dwarf was Sir Jeffery Hudson, who was born at Oakham in 1619. He made his first appeal to fame when he was presented by the Duchess of Buckingham to Queen Henrietta Maria as he stepped out of a pie. From the age of eight till thirty he was only eighteen inches high, but afterward suddenly shot up to three feet nine. He became a well-known courtier and was entrusted with several matters of delicacy. He did not lack courage for he fought two duels, one with a turkey-cock, celebrated in the verses of Davenant, and another with Mr. Crofts, who came to the meeting with a squirt. A more serious encounter, however, followed, for little Jeffery, who was mounted on horseback to compensate for his inferior height, shot his opponent dead. He was twice made prisoner, once by the Dunkirkers as he was returning from France, and once by the Barbary pirates. On each occasion he was soon ransomed. He eventually, however, fell on evil days, for he was accused of participating in the popish plot and was sent to the Gate House, where he died in 1682.

About the same period, or somewhat earlier, Charles I. had a page at his court called Richard Gibson, who was remarkable for his small size, and was, appropriately enough, a miniature painter. He married Anne Shepherd, the dwarf of Henrietta Maria, the ceremony being performed by Edmund Waller. Together they only measured two inches over seven feet. Evelyn designated Gibson as a "compendium of a man," and the pair were painted hand in hand by Sir Peter Lely. Mistress Gibson had nine children, five of whom survived and were of normal size. She died at the age of eighty, and her husband at seventy-five.

One of the most celebrated dwarfs was a Polish gentleman, Joseph Borwilaski, who became noted throughout Europe as a handsome man, a wit, and something of a scholar. His parents were tall, but three of his brothers were small. He was born in 1739, and died at the advanced age of ninety-eight in the city of Durham, where, by the irony of fate, he is buried by the side of the Falstaffian Stephen Kemble. His height was thirty-nine inches. Diderot wrote a history of the family.

Another remarkable dwarf was Richebourg, a servant and pensioner of the Orléans family, who died in Paris at the age of ninety. He was only twenty-three inches high, and his diminutive size was taken advantage of during the stirring times of the Revolution when, masquerading as an infant in his nurse's arms, he carried despatches in and out of Paris.

Coming to more recent times we may mention Charles Stratton, or "Gen. Tom Thumb," one of the greatest of Barnum's successes. At birth he was above the normal weight of the new-born, but ceased to grow when five months old His height at that time was less than twenty-one inches. He created a sensation in Europe and amassed a large fortune.

Perhaps the next most striking sensation has been the "Lilliputians," a troupe of singers and comedians possessing much talent as burlesquers. They were probably the same individuals who were examined by Joachimsthal in Germany.

Many of the recorded dwarfs have been very diminutive. Buffon mentions dwarfs only twenty-four, twenty-one, and eighteen inches high, and describes one who, when thirty-seven years old, measured sixteen inches, whom he considers to have been the smallest person on record. The "Princess Topaze," a French dwarf, is twenty-three and a half inches tall (or rather short ?), who weighs only fourteen pounds. Her parents were of normal size.

On consideration of the facts recorded in the above remarks we are led to certain important conclusions. Most dwarfs have been well proportioned, without deformity, and of average or more than average intelligence. Some of them have been persons of great vigor and force of character. In fact they may be said to differ but little from ordinary individuals save in the one point of size.

Dwarfs fall naturally into two classes: Those that are diminutive at birth and subsequently develop slowly, so that they always remain more or less stunted; and those that are of normal or even more than normal size at birth and later cease to grow. Authentic information as to the size of dwarfs at birth is hard to obtain. We may, however, correctly infer that they are often below the average size, for dwarfed mothers have frequently borne children in a natural way, and physical considerations would preclude us from coming to any other conclusion. Conversely, normally developed mothers have not infrequently given birth to dwarf children. Instances are on record of new-born infants weighing a pound and three-quarters, or even less, at full term. The subsequent hisory, however, of these children is unfortunately often unknown. Home (Philosophical Transactions of the Royal Society of London, 1825) speaks of a child borne y a woman following the Duke of Wellington's baggage train, which weighed at birth only one pound, and measured between seven and eight inches long. At the ge of nine it was only twenty-two inches high. This s said to be the same child, called Caroline Crachami, whose skeleton is in the museum of the Royal College of urgeons near that of O'Byrne, the "Irish Giant."

Inasmuch as in the cases of dwarfism that we have so ar been considering the parts are perfect in form and the mbs are in the normal proportion to the trunk, although he body as a whole is defective in size and weight, it as been suggested that here we really have to do with condition of infantilism which may be defined as a state f imperfect and delayed development, whereby the individual preserves the characteristics of childhood long fter these should have disappeared. This view is supported by the fact that in many cases of dwarfism the ead is proportionately large, as it is in the infant, the enitalia are undeveloped, and the signs of puberty are bsent or delayed. Joachimsthal (*Deutsche med. Woch.*, 99, xxv., SS. 269–271, 288–290), studying with the oentgen rays a troupe of exhibiting lilliputians, found at bone formation was imperfect, the various centres ossification being strictly comparable to those of a ild, although the individuals in question were about irty years of age. Undoubtedly, in some at least of e deficiencies complete development and function may entually be attained. For instance, many of these warfs have proved themselves capable of propagating eir kind. One cannot fail to be struck also with the ct that dwarfs frequently reach an advanced age, the verse of what is found in the case of that other consting anomaly of development, gigantism. This sugsts certainly not a defect in the vitality of the body a whole, but rather an anomaly in the nature and diction of the growth. The normal balance between ucture and function is upset and the individual may ssess the mind and faculties of the adult in the body the child.

With regard to the etiological factors at work in the oduction of dwarfism we are compelled to admit that r knowledge is far from complete. Our views theree must partake largely of the nature of hypotheses. o to the present time but few cases of dwarfism have en studied, and it is chiefly upon the facts gleaned m these and the results of experimentation that our erences must be drawn.

The condition of dwarfism is clearly but one aspect of e larger question of dystrophy or dysgenesy. Conseuently it can be apprehended only by a reference to elementary principles governing the formation and owth of tissues.

The developmental forces concerned in the elaboration a new individual may be inadequate to bring the pros to completion. If they are totally inadequate, death the embryo results. Short of this extreme result, hower, the nutritional processes may be so modified that get a deficiency or excess in growth of the organism, er in part or as a whole, or they may be so perverted that we have actual malformation and deformity. There is, therefore, a close relationship between dwarfism, gigantism, malformations, and monstrous births. The peculiarities of development that result in such anomalies may be inherent in the sperm cell or ovum or both, and in this sense are inherited, or they may be due to causes operating on the ovum subsequently to fertilization, either before (intra-uterine acquired causes) or after birth (post-natal acquired causes). We have, therefore, to take into account primitive peculiarities of cell substance on the one hand, and external causes, nutritional or mechanical, acting on the fruit, on the other.

In this particular certain general considerations are worth noting. Thoma ("Untersuchungen über die Grösse und das Gewicht der anatomischen Bestandtheile des menschlichen Körpers im gesunden und im kranken Zustande," Leipzig, 1882) has called attention to what might be called a general "law of deviation." In adults the normal length of the body is on an average 169 cm. in the male and 163 cm. in the female, while the average weight is 60 kgm. and 56 kgm. respectively. Considerable variations on either side of this norm may occur. Taking a large number of individuals, in one-half the amount of deviation will be anywhere between 0.0 and 3.8 cm. In accordance with the law he has formulated, the fifth multiple of this figure when added to or subtracted from the normal average height will give the outside limit of giant or dwarf growth, and will be reached only once in every thousand cases. According to this an adult would be regarded as a dwarf if the height fell below 163 minus 19 cm., or 144 cm. Similarly 5 kgm. is the approximate aberration in weight from the normal in the adult. The fifth multiple of this, 25 kgm., subtracted from 56, gives 31 as the upper limit in weight for dwarf growth. With regard to weight, we have, of course, to be careful to exclude such conditions as marasmus and loss of height from spinal disease. In the case of the new-born the normal average in length is 50 cm. and the weight 3.2 kgm. The amount of deviation is approximately 1.4 for length and 0.28 for weight. The upper limit for dwarf growth in mature infants at birth would therefore be 43 cm. and 1.8 kgm. respectively. Some allowance for individual peculiarities must be made, for many children that are diminutive at birth make up for the deficiency by rapid growth afterward, while, again, some children that are normal in size and weight at birth subsequently become retarded in their growth and development. This "law," while it gives us convenient data for classification, is, needless to say, very far from being an explanation of the anomaly.

Again, certain adventitious circumstances, acting apparently on the germinal cells, may play a part. It has long been known to stock-raisers that continued in-breeding will result in the production of diminutive offspring. And it is said that after Napoleon's campaigns there was a diminution of from one to two inches in the stature of the French people. This has been attributed to the fact that the strongest and best developed males were drawn for military service, but, no doubt, poverty, famine, and disease, affecting the people as a whole, were important factors. These observations suggest that defective physical development on the part of one or both progenitors may lead to insufficient vitality, or what might be termed "relative vegetative inertia" on the part of the germinal cells. This leads us to the consideration of the importance of heredity in this connection.

The inheritance of a developmental anomaly is well illustrated in the case of polydactylism. This peculiarity has been known to persist for three, four, or even five generations, although it may in time be eradicated by marriage with normal persons. The Foldi family, belonging to the Arabian tribe of Hyabites, all have twenty-four digits. They never marry outside the family, and the anomaly is so constant that any child having the normal number of digits is put to death as the offspring of adultery. Reference will be made later to the influence of pressure of the amniotic sac upon the growing embryo in the production of this and other deformities, but it would be absurd to suppose that such a cause could be present throughout several generations and in a whole race. We are driven to conclude that there must have been some anomaly in the formation and development of the "Anlage" arising in the earlier stages of embryonic life. This being so, it would not be surprising to find the influence of heredity somewhat marked in the condition of dwarfism. As a matter of fact, dwarfism is not invariably an expression of a hereditary peculiarity, although sporadic cases may occur in several generations derived from the same stock. Certain parents nevertheless seem to have a tendency to produce dwarfs. To cite only one example, the celebrated Borwilaski had a brother and sister who were dwarfed. The fact, however, that while certain members of a family may be dwarfs, others may be normally developed indicates that the cause, whatever it be, is not a constantly acting one, or else that there are a number of factors which must be correlated before the given result will take place. That the issues involved may be very complex is well illustrated by an extraordinary instance related by Ekman ("Dissertatio medica descriptionem et casus aliquot osteomalaciæ sistens," Upsaliæ, 1788) where dwarfism and osteopsathyrosis were associated through three generations. The ancestor could not walk because of deformity. He had four children, of whom one son was a dwarf and one daughter was small and deformed. This son begat by a healthy wife a son who had curved extremities, and was liable to fractures on the slightest provocation. This son in turn married a healthy woman who gave birth to a son who had so many fractures that when he reached adult life he could not move, and a daughter who was dwarfed and also suffered from multiple fractures in childhood. Apparently, then, heredity may manifest itself, not only in the rate and amount of growth, but also in the structure and composition of the tissues. Moreover, these two factors, simple growth and organic formation, are not always correlated, and may even be antagonistic. Numerous exceptions to hereditary transmission, however, occur, for when both parents have been dwarfs, the offspring have frequently proved to be normal in size and proportion. What, however, is an occasional anomaly in the case of civilized peoples is a constant racial characteristic in certain of the African tribes, such as the Akkas and Bushmen. This can hardly be explained on any other assumption than that an acquired peculiarity, due to unfavorable environment, has become transmitted and in time impressed upon a great number of individuals, unless we are prepared to accept the other alternative that all races of mankind were originally much smaller than they are at present, and, owing to natural selection and the growth of civilization, gradually developed into a superior organization, a view that, at all events, is not supported by history or tradition. Heredity probably has the same bearing in dwarfism as it has in the case of other anomalies; no more and no less.

The influence of extraneous circumstances on the vegetative power of the germinal cells is well illustrated by some comparatively recent and most suggestive experiments.

In experimenting with the fertilized eggs of some of the humbler forms of life, Roux showed that if, in the two-cell stage, one of the blastomeres be destroyed, the other will regenerate the missing half and eventually give rise to a complete embryo. Endres, Walter, and Morgan have come to similar conclusions in the case of the frog, with the additional observation that the peculiarity is characteristic of the earliest stages only and may be entirely suppressed. In 1891 Driesch separated, by shaking, the blastomeres of the sea urchin's egg when in the two- and the four-cell stage. Blastomeres thus separated produced in time a complete blastula, and the resulting gastrula was a perfectly formed dwarf of one-half or one-quarter the natural size, as the case might be. Zoja, too, in some remarkable experiments on the medusa was able to produce dwarfs one-sixteenth of the normal size. Morgan has further discovered the important fact that either a half embryo or a complete half sized dwarf will result according to the position of the blastomere. If, after one blastomere is destroyed, the other be allowed to retain its normal position a half embryo is always produced, as Roux had already shown. If, however, the blastomere be inverted, it gives rise either to a half embryo or a whole dwarf. In this connection we might recall certain early experiments of Saint Hilaire, who produced dwarf chickens by shaking the egg in the direction of its long axis. Thus it would appear that a rearrangement of the cell material may restore that equilibrium of the entire ovum necessary for the production of a whole embryo. This extraordinary power is, however, less marked in the higher forms and is ultimately lost. In view of the fact, however, that parthenogenesis, which is a constant occurrence in some of the lower forms of life, is sometimes to be observed even in such a highly organized creature as the hen, and in fact has been advanced by some authorities to explain the development of certain tumors of the human ovary, it is not impossible that anomalies in the segmentation of the ovum in human beings, may, although rarely, give rise to one type of dwarf at least, namely, that dwarfed from birth. Two factors would appear to be necessary: some cause to blight one-half of the ovum in the very earliest stage of its development, and another producing a disturbance of the cell equilibrium. As to what these factors may be, whether developmental, traumatic, or inflammatory, we have absolutely no information. One or two facts may possibly point us in the right direction. Malposition of the fertilized ovum as a whole may be brought about by intratubal and intra-uterine inflammation, instances of this being tubal gestation and placenta prævia. It is not inconceivable, therefore, that endometritis and deciduitis might lead to blighting of a portion of the embryo and disturbance of protoplasmic equilibrium. That a modification of external conditions does have a profound effect on the developing ovum, in some animals at least, we have ample proof. Dareste, by incubating hen's eggs at a temperature more elevated than that usually employed, got early development and dwarf formation. Gerlach and Koch ("Ueber die Produktion von Zwergbildungen im Hühnerei auf experim. Wege," *Biol. Centralbl.*, xxii., 1884) also obtained a retardation of development and dwarf growth by varnishing eggs so as to exclude all but a small amount of air.

The effect of primitive peculiarities inherent in the germinal cells in producing developmental anomalies of the Anlage has already been noted in regard to polydactylism, and it is now pertinent to inquire in how far deficiencies in the formation of those structures more especially concerned in the general maintenance of nutrition, namely, the cardiovascular and nervous systems, and the thyroid gland, are of importance in the production of dwarfism.

If the circulatory apparatus be deficient either in the size and extent of the vessels or in the formation of the chambers and valves of the heart, it is obvious that the circulation of the blood must be inadequate for the needs of the organism, which consequently may be inhibited in its growth. Long ago Virchow pointed out the association of cardiovascular hypoplasia with other developmental defects, such as scanty production of the pubic hair and small size of the genitalia, conditions that may be regarded as manifestations of partial infantilism, if we take the view of Hertoghe, that there is such a thing as partial infantilism ("Die Rolle der Schilddrüse bei Stillstand und Hemmung des Wachstums und der Entwicklung," Spiegelberg, München, 1900). Gilbert and Rathery (*Presse méd.*, May 7th, 1900) have, it may be mentioned, found a moderate grade of dwarfism in some cases of mitral stenosis.

With regard to the influence of the nervous system in the production of dwarf growth the available evidence is not conclusive. The close relationship of the central nervous system to the nutrition of the tissues is of course admitted by everybody, and we are aware how often injuries to certain ganglion cells or nerve trunks are followed by atrophy or other degenerative disturbance. It would not be surprising, then, to find that a defective development of the central nervous system might lead to aplasia or hypoplasia in the embryo. Of course the more extensive defects of the central nervous system, as anencephaly and amyelinia, are incompatible with life, and consequently cannot be adduced as conclusive evidence on the subject of dwarfism. As a matter of fact, however, whatever information we possess seems to negative the position that dwarfism is a neurotrophic disorder. For instance, as Cruveilhier has shown, the most extensive hydranencephaly may exist without a trace of defective development in the rest of the body, and Vogt, Klebs, and Aeby have pointed out that in microcephaly the individual as a whole may in other respects be well developed. The most we can say is that certain forms of local hypoplasia may with some probability be referred to central nervous disturbances. The probability is increased when in a child with such a defect the process extends subsequently, as in a case recorded by Emminghaus (*Deutsches Archiv f. klin. Med.*, Bd. ii., S. 96, u. Bd. xii., S. 49), where there was congenital microplasia of one arm followed in the tenth year by a trophoneurosis of the eye and corresponding side of the face.

That the thyroid gland exerts an important and often controlling influence in the processes of nutrition cannot now be denied. In how far athyroidea has to do with dwarfism is still a moot point. The whole question as to the relationship of the thyroid gland to myxœdema, cretinism, and deficient development generally will be dealt with more at length shortly. Suffice it to say here that there is considerable evidence to support the view that there are many minor forms of cretinism in which the most striking and characteristic features are absent, and where the analogies to dwarfism are close. Küster extirpated the thyroid gland in a boy of fourteen, whose growth was thereby arrested so that he always retained the characteristics of a boy of that age. Eiselsberg (*Langenbeck's Archiv*, Bd. xlix., 1895) removed the thyroid in two lambs a week old. At the end of six months they weighed 10 and 14 kgm. respectively, while the controls weighed 35 kgm. The disturbance was general and involved the brain as well as the skeleton. Kappeler also found in a boy of twelve and a half years, who had been deprived of the gland, that he did not grow and developed some of the symptoms of myxœdema. It may well be, therefore, that infantilism, as Brissaud holds ("Leçons sur les maladies nerveuses," Paris, 1895), is simply an attenuated form of cretinism. Additional support is given to this view by the fact that some of the cases have been improved by thyroid feeding. Cases of this kind have been recorded by Wunderlich (*British Med. Journ.*, ii., p. 1420, 1897) and Dukes (*British Med. Journ.*, i., p. 618, 1898). In Wunderlich's case palpation proved the thyroid to be extremely small. In this connection also should be cited an interesting case of Sulzer's (*Deutsche Zeitschrift f. Chirurgie*, 1893) in which a goitrous thyroid was removed from a boy twelve and a half years of age. In five years he was a typical cretin. He then began to improve and in four years had regained the normal condition. It was found that a portion of the gland had been left behind at the operation, and that this portion began to grow some eight years afterward. In the same way the compensatory development of an accessory thyroid has an important bearing on the question of cretinism. These facts afford a probable explanation for such curious cases as that of Sir Jeffery Hudson, who, as we have seen, after remaining eighteen inches high for twenty-two years, suddenly shot up to three feet nine inches. Even if we are prepared to admit that infantilism is due to athyroidea, the identity of infantilism with dwarfism is not beyond cavil. At most can we say that the explanation may hold good for some of the cases. For, as Lorain was the first to point out, instances are met with in which there is no disturbance of the thyroid gland, and the defect in size is not true infantilism, but rather to be attributed to premature epiphyseal ossification.

So far we have been discussing the relationship of defective organization of the "Anlage" of the various systems to the question of general hypoplasia.

We pass on now to the question of intra-uterine malnutrition. In this connection ill health or improper diet affecting the mother or a local anomaly of placentation is the chief factor concerned. The former act by bringing a poor quality of blood to the support of the fœtus, and the latter presents a hindrance to the free interchange that should go on between the maternal and fœtal bloods. The existence of syphilis, tuberculosis, or chronic alcoholism in the mother might be expected to produce its effect upon the offspring, largely in the form of lowered vitality and increased susceptibility to disease. It is suggestive in this connection that the Japanese are in the habit of producing dwarf pups by feeding the mothers with alcohol. Charrin, furthermore, could produce a similar result by the injection of ptomaïns. Yet the children of mothers the subjects of long-standing disease or cachexias are by no means always diminutive or poorly nourished. The vitium shows itself, not so much in immediate anomalies of physical development, as in disordered function and defective reserve power. Much discussion has centred round the question as to whether there is such a thing as fœtal rickets. Rickets generally makes its appearance during the first or second year of life, after the sixth month, and is commonly attributed to insufficient and improper alimentation, although unhygienic surroundings may also play a part. It is not impossible that analogous causes, operating during intra-uterine life, might produce the same effects. Rickets is not hereditary, although congenital influences may play a part. In former times, and indeed to a large extent even in these days, the term "fœtal rickets" has been used in a very loose way to include several affections characterized by imperfect bone formation, such as syphilis, osteogenesis imperfecta, and chondrodystrophia fœtalis, which are now, thanks to recent studies, separated fairly well one from the other. It is now the general censensus of opinion that congenital rickets, in the sense of a rickets that has run its course previous to birth, does not exist. To this, however, we shall return.

In one or two cases the study of dwarf fœtuses has revealed the fact that there is an abnormal relationship between the fœtal placenta and the maternal structures. The chorionic villi were scanty and were composed of thin strands of connective tissue covered by an abnormally thick layer of epithelium, while at the same time the projections of the maternal decidua did not extend through the thickness of the fœtal placenta, as is usually the case. The explanation of this that has been offered is that there was a defective development of the decidua, but this is almost certainly incorrect. Chipman ("Observations on the Placenta of the Rabbit," "Studies from the Royal Victoria Hospital," Montreal, vol. iv., December, 1902) has shown that the more intimate connection between the fœtal and maternal parts is brought about by a process of absorption, the ectodermal cells of the chorionic villi proliferating and invading the openings of the uterine glands and extending along the sheaths of the blood-vessels. The maternal tissues are thus eroded as it were, and are quite passive in the matter. It may well be, then, that such an anomalous development of the placenta is due, not to malnutrition and imperfect cell growth on the part of the mother, but to a primary fault in the growing embryo that evidences itself in an imperfect development of the placenta. Apparently, however, before such an abnormality can result in dwarfing of the fruit it must be quite extensive, for the given result does not always follow. As Langhans has pointed out, a similar peculiarity of placentation occurs in cases of tubal gestation, where the fœtus is usually well developed.

Further, the proper interchange of blood and nutriment through the placenta may be gravely interfered with owing to inflammatory disturbances. Here syphilis plays a leading rôle. As is well known, in syphilis hereditaria tarda there is a delayed development of the bony and muscular systems, so that a young man of twenty may look like a boy of ten or twelve. With this there is often an infantile condition of the genitalia and the hair on the pubes and other parts is slow in appearing. The characteristic lesion of syphilis in the placenta is endarteritis, which leads to extensive destruction of the vascular area, with degeneration, atrophy, and fibrosis of the region involved. The placental circulation must in such cases be greatly interfered with. In syphilis, however, other factors enter. We have to admit that the presence of so serious a disease in the parent, usually the father, must have a tendency to lessen the vitality of the germ cell, to say nothing of the presence of the germ of the disease (the existence of which on analogy we can hardly deny) in the fertilized ovum, with all that this implies.

Hitherto we have been discussing what might be called *primary* or *essential* dwarfism (microsomia) in which the predominating element is a deficiency in the vegetative energy of the cells. The affected persons are in fact normal individuals save in the one particular of size and weight. Besides this, however, we have to recognize another class of cases that clearly belong to a different category. I refer to instances of *secondary* or *symptomatic* dwarfism. Here, while the height of the body is below the normal, the weight is not so strikingly diminished as in the true dwarfs. The main feature is, however, that in addition to general hypoplasia, there are evidences of pathological changes in the tissues, particularly in the bones, leading to asymmetry, deformities, fractures, or malformations. The defects are structural as well as nutritional. Just at this point it may be remarked that the exact nature of these cases presents one of the most difficult problems in etiology. In former times many cases of congenital dwarfism of this type were put down to syphilis, rickets, or cretinism. It was soon found, however, that there were some important points of distinction between certain of the cases. The typical features of cretinism were not always present, nor did the disease, if rickets, conform to the picture of the ordinary post-natal affection. These considerations have led investigators to recognize several distinct types, which are by some regarded as separate entities. We have, therefore, to consider in this connection rachitis, cretinism, osteopsathyrosis, chondrodystrophia fœtalis, and osteogenesis imperfecta, affections that agree in this that with more or less stunting of the body there are structural modifications of the bones of an obviously pathological nature. The amount of confusion that has involved the subject is sufficiently indicated by the number of names that have been proposed for the condition—fœtal rachitis, pseudorachitism, cretinoid dysplasia, chondritis fœtalis, micromelia chondromalacica, achondroplasia, chondrodystrophia fœtalis. A decided step in advance has been made through the researches of Kaufmann ("Untersuchungen über die sogen. fœtale Rachitis," Berlin, 1892, u. Ziegler's "Beiträge," 1893, xiii., S. 32–64) who introduced the name chondrodystrophia fœtalis. Here the type of dwarfism is micromelic and the lesions are usually symmetrical. The body is plump, the micromelia rhizomelic, the head large, and the hands often show the so-called "trident" deformity. There are, however, notable differences in the length, curvature, and consistence of the bones of the extremities, and in the configuration of the skull. Kaufmann, consequently, recognizes two groups: one, in which there is a distinct cretinoid appearance of the skull and face, namely, a deeply sunken nose, prominent eyelids and lips, thick cheeks, and large mouth; and another, in which the nose is flattened and retracted as a whole. In the former type the bone is of good consistence although somewhat more vascular than normal, while in the latter the bone is soft. No hard-and-fast line can be drawn between the two forms, and Kaufmann regards them as manifestations of the same process, the differences being due to the chronicity and intensity of the process. The retraction of the root of the nose is usually said to be brought about by premature ossification and synostosis of the os tribasilare. The ethmoid is also somewhat shortened, and in some cases may be the only part affected. Klein has observed well-marked craniotabes in some cases. In some, too, there may be beading at the costochondal articulations, and defective development of the pelvis, glenoid, and cotyloid cavities. Lordosis may also be a marked feature, and Regnault (*Bull. et mém. de la Soc. d'Anat.*, 1901, lxxvi., pp. 559–560) has found the vertebræ involved. The disease begins in fœtal life, running its course usually, as it is believed, from the third to the sixth week. As a consequence the bones affected are the base of the skull, the long bones, the ribs, and the pelvis. The bones formed in membrane, those that in late fœtal life are mainly cartilaginous, usually escape. Kaufmann has described three sub-classes in chondrodystrophia: Chondrodystrophia malacica, in which the bone is soft; C. hypoplastica, in which there are evidences of retarded growth; and the C. hyperplastica in which the epiphyseal ends of the long bones are greatly enlarged. The periosteal ossification is normal, so that the bones become plump and thick, although somewhat irregular, but the growth in length is disturbed owing to faulty ossification at the epiphyseal junctures. Ingrowth of the periosteum at the epiphyseal lines may occur. Microscopically the cartilage cells are deficient in growth, being spindle-shaped and irregularly arranged, while the hyaline matrix is more or less soft and homogeneous. It is not improbable, however, although the majority of children thus affected are stillborn, that when the affection is of mild type or arises late on in fœtal life, existence may be prolonged for some time. Parrot has met with an example in a child seven and a half years old, who measured 94 cm. in length. Certain changes in the bones of the hands, notably in the fingers, seem to prove that the disturbances of ossification may go on at a later period than that above indicated. (See Thompson, *Edin. Med. Journ.*, 1892–93, vol. xxxviii., pp. 1109–1113, and Turner, *Practitioner*, 1899, vol. lxiii., pp. 263–277.) Thompson (*loc. cit.*) has met with two instances at the ages of thirty-six and thirty-nine, and others have been described by Osler (Trans. Amer. Cong. Phy. and Surg., 1897, vol. iv., pp. 190–192), Abt (*Archives of Pediatrics*), Cestan, "Nouvelle Iconographie de la Salpêtrière," 1901, xiv., 277–289), Apert (*Ibid.*, pp. 290–298), and Baldwin (*Medical News*, 1890, vol. lvii., pp. 138–141).

The exact relationship of the disease, called by Vrolik and Stilling (*Virch. Archiv*, 1899, cxv., SS. 357–370) osteogenesis imperfecta, to chondrodystrophia, is still *sub judice*. The studies of Stilling, Hildebrandt (*Virch. Archiv*, 1899, clviii., SS. 426–444), and Harbitz (Ziegler's "Beiträge," 1901, xxx., SS. 605–628) go to show that it is a definite intra-uterine process. There is clearly some defect in the process of ossification, for the bones are soft and brittle, with the result that fractures and deformities are common. Microscopical study has shown that the trabeculæ are few in number, irregular, and imperfectly formed. There is no continuous system of trabeculæ with Haversian canals and lamellæ as in normal bone. A point of great interest is the extraordinary manner of ossification of the skull. The calvarium is formed not of continuous bony plates, but of a multitude of small mosaics, sometimes touching one another, but also attached by bridges of periosteum and dura. In a remarkable case described by Stilling, the cranial covering consisted of a membranous sac which contained scattered bony spicules. So far as is known there is no synostosis of the basal synchondrosis in this disease. While the affection has hitherto been found only in the new-born or in very young infants, it is not necessarily fatal, and Harbitz is inclined to think that some cases of dwarfism that have been regarded as examples of fœtal rickets or chondrodystrophia may have been osteogenesis imperfecta. As in chondrodystrophia porosity of the bones occasionally appears to depend on hereditary conditions, and Bircher (Lubarsch u. Ostertag, "Allg. Aetiologie," Wiesbaden, 1896, S. 53) has found osteoporosis in the case of a chondrodystrophic dwarf (*cf.* also the case of Ekmann, referred to above). We are, therefore, not prepared to believe with Paltauf ("Ueber den Zwergwuchs," Wien, 1891) that the two affections are not related.

To rickets chondrodystrophia bears much resemblance, although there are several differences. In both there is enlargement of the epiphyseal ends of the long bones (chondrodystrophia hyperplastica), the long bones may be curved, the ribs beaded, and there may be spinal and pelvic deformities. In rickets, however, the arms are usually long. Periosteal bone formation is also interfered with. The periosteum is readily stripped off and the underlying bone is softer and more spongy than normal. As the condition heals the bone becomes unusually plump and dense. Basilar synostosis does not occur in rickets. Microscopic study has shown that the epiphyseal zone of proliferation in rickets is thicker than normal, irregular in outline, soft, and very hyperæmic, so much so that Kassowitz believed the lesions to be of inflammatory origin.

The microscopical appearances of the growing ends of the bones in chondrodystrophia are, however, quite different from those in post-natal rickets. No clear evidence of the existence of rickets originating during intra-uterine life is forthcoming, yet there is a parallel between chondrodystrophia and rickets, for, as is well known, post-natal rickets, if severe, results in the stunting of the growth of the affected individual, and cases of extreme dwarfism have been met with. The lesions are characteristic. The skull is large, although the face is relatively small. The fontanels remain open for a prolonged period, and bone in certain regions, especially the occipito-parietal, may be so thin as to give way under the pressure of the finger (craniotabes). The forehead is usually large and square, owing to the formation of flat hyperostoses over the frontal eminences. The sternum projects and the sides of the chest are drawn in (pectus carinatum). The spine is often curved and the extremities become greatly deformed owing to the weight of the body and muscular action. The pelvis is contracted; dentition is delayed and the teeth are small and badly formed. The condition is by many believed to be due to infection or possibly auto-intoxication. This view is supported by the experiments of Morpurgo (*Centralbl. f. Path.*, 1902, xiii., S. 113), who showed that rickety changes in the skeletons of young white rats could be produced by the injection of cultures of a diplococcus. The lesions in rickets, however, are so unlike those of chondrodystrophia in important particulars that it is unlikely that an infective cause is at work in the latter disease. Differentiation between chondrodystrophia and rickets may be made by attention to the following points: The dwarfism in the former is micromelic; in the latter not. Periosteal bone formation is not interfered with in chondrodystrophia, while it is in rickets. In healed rickets the bone is abnormally dense; not so in chondrodystrophia. Basilar synostosis does not occur in rickets. In rickets you do not get "trident deformity" of the hands. Developmental anomalies, like cleft palate and polydactylism, are not found in rickets. Osteogenesis imperfecta is recognized by the fragility of the bones, the peculiar ossification of the cranium, and the lack of basilar synostosis.

It is a suggestive and a striking fact that while we are able to draw these distinctions between the type cases of chondrodystrophia, osteogenesis imperfecta, and rickets, there exist borderland cases in which some of the features of these diseases may be combined. Such a one is that reported by Hektoen ("Anatomical Study of a Short-limbed Dwarf," *Amer. Jour. Med. Scien.*, May, 1903), in which in a micromelic dwarf, forty-five years of age, there were one hundred and seventy-two Wormian bones in the skull, without premature synostosis of the os tribasilare, with shortness and curvatures of the long bones, enlargement of the articular ends, curvatures of the spine, deformity of the pelvis, osteoporosis and multiple fractures, and a fibroid thyroid. A case presenting features both of chondrodystrophia and osteogenesis imperfecta has been described also by the Countess von Geldern-Egmond ("Beitr. zur Casuistik der sogenn. fötalen Rachitis," Inaug.-Diss., Zurich, 1897)

The etiology of these interesting conditions is still largely unknown. Heredity appears to be a factor in some cases. In one case, recorded by Porak ("Beitrag zur Histologie und Funktion der Schilddrüse," Inaug.-Diss., Königsberg, 1892) a dwarf gave birth to one healthy child and a second with all the signs of the so-called "fœtal rickets." Guéniot (*Bull. et mém. de la Soc. Obstet. et gynécol. de Paris*, January, 1898) recounts the operation of Cæsarean section on an achondroplastic dwarf, the child being similarly affected. The parents of chondrodystrophic dwarfs as well as their children are nevertheless often healthy. Heredity seems then to play a minor rôle. The influence of heredity in the case of polydactyly has already been dwelt upon, and it is a curious fact that polydactyly may sometimes be associated with dwarfism. An instance of this will be found in *Hutchinson's Archives of Surgery* for April, 1898, where there is given an illustration of a micromelic polydactylous dwarf, copied from Theodore Kerckring's "Spicilegium Anatomicum," published in 1670. The drawing is not entirely to be relied upon, but it is clear that the limbs were too short for the trunk. Both the hands have seven digits; the right foot has eight and the left nine. The condition is not perfectly symmetrical, for in some cases two of the metacarpal or metatarsal bones are welded together. The long bones are plump, and, so far as it is safe to judge from the imperfect sketch, the ends appear to have been enlarged. The orbits are deformed, the two halves of the lower jaw are already united, and the ribs are short and badly formed. It is clear that here we have an abnormality of development in few respects comparable to rickets. It may be that here, as in simple polydactylism, we are dealing with a primary vitium of development inherent in the germinal cell. This view is supported also by the observation of Kirchberg and Marchand (Ziegler's "Beitr. zur path. Anatomie," Bd. v., 1889), who found cleft palate in a chondrodystrophic infant. One of Bowlby's cases, also, reported as congenital cretinism but really an instance of chondrodystrophia, had a cleft palate and a deformed nose. The right foot had six metatarsal bones but seven toes; the left foot had seven toes.

There is, however, another possible explanation. Recent observations have shown that many forms of hypoplasia, non-closure of sutures, and, in fact, the most extreme deformities may result from intra-uterine pressure. The simple weight of a limb resting on a band has been sufficient to erode the soft tissues to the bone. Twisting of the cord about a limb may lead to dwarfing or amputation. The pressure of bands traversing the amniotic sac is also a well-recognized cause of even more extreme deformities, such as anencephaly and craniorachischisis. Dareste believed that a contracted amnion was an important cause of hypoplasia.

In Klebs' text-book of "General Pathology" (vol. ii., 1889, Jena) is an interesting illustration representing a microscopical section through the proliferating end of one of the long bones in a micromelic dwarf. The growing cartilage cells are closely packed together, flattened, with their long axes at right angles to the long axis of the bone. The appearances could not be due to alterations in the ground substance which seemed to be normal, but could be attributed only to the effects of external pressure. This would, of course, lead to inhibited and imperfect ossification. The effects of intra-uterine compression are well illustrated by the experiments of Fol and Warynski (Thèse de Genève), who brought external pressure to bear upon a growing embryo. They found that the head was the part most amenable to pressure, and could to some extent be restrained in its growth. Warynski, also, by exerting pressure at the site of fusion of the two primitive cardiac rudiments, was able to produce a double-hearted monster. Klebs (*loc. cit.*, p. 306) refers to a most remarkable case in which a contracted sac led to a singular malformation. In an ectopic gestation the fœtus was found in a tight sac within the transverse mesocolon. There was syndactylism in the upper extremities and polydactylism in the lower. From the recorded cases it would appear that contraction of the amnion does not lead to dwarfing of the fœtus as a whole, but that certain parts are more liable to be affected, as the extremities and head. In this connection also may be remembered the fact that hydramnios is apt to be associated with grave deformities, such as exencephaly and spina bifida, and has been found in a case of osteogenesis imperfecta. The effect of intra-uterine pressure has also been emphasized by von Franqué ("Ueber sogenan. fœtale Rachitis," Sitzungsberichte der physicalisch-mediz. Gesellsch., Wurzburg, Jahrg. 1893, S. 80).

It is on the ground of the obvious errors in development which are sometimes associated with chondrodystrophia, and which can only be referred to peculiarities of the Anlage, that Virchow objects to the term chondrodystrophia introduced by Kaufmann. Virchow points out that the condition imperceptibly shades into a pronounced developmental anomaly (*Missbildung*), which is finally represented by the phokomelia of Saint Hilaire.

The small stature, the peculiar facial configuration, and the enfeeblement of mental power, with other minor abnormalities found in some cases of chondrodystrophia, have induced the suspicion that some of these cases of dwarfism are really cases of cretinism. The difficulties in the way of differential diagnosis are great. Thus Dolega, Bernard, and Bircher have pronounced certain cases to be instances of cretinism, and yet a subsequent examination proved them to be Kaufmann's chondrodystrophia, and conversely, Neumann, Scholz, and others have described instances of cretinism as fœtal rickets. The difficulties in the way will be readily comprehended if one considers for a moment the lesions in a typical case of cretinism. In the cretin the stature is almost always stunted, Maffei in twenty-two cases out of twenty-five finding the height to be less than 140 cm., while several were under 95 cm. The limbs and trunk are disproportionate. The head is usually relatively large, the top flat, and the occiput prominent, although microcephaly has been found. The fontanels and sutures remain open for a long time. The root of the nose is retracted, and the organ is short and thick with large wide nostrils. The lips and tongue are enlarged. The teeth appear late and are large. The first dentition usually persists throughout life. There is as a rule no hair on the pubes and in the axillæ. The sexual organs are poorly developed, and puberty, if it occur at all, is late. With regard to the finer structure of the bones in cretins, Langhans (*Virch. Archiv*, 1892, cxxviii.) found that the cartilage cells were small, spindle-shaped, and anomalously arranged, being longitudinal to the axis of the columns. The rows were also often interrupted. The bony trabeculæ were shortened and the marrow spaces in the youngest portions of the bone were large and widely separated. The resemblance to Class I. of Kaufmann's chondrodystrophia is close. Typical cretinism is endemic and associated with goitre. Chondrodystrophic dwarfism is sporadic. Can, then, chondrodystrophia be sporadic cretinism? The recorded cases of chondrodystrophia go to show that the disease is of intra-uterine origin, and so far no evidence is forthcoming to prove that the affection ever arises subsequently to birth. Cretinism is said to be congenital in some cases, but the symptoms usually appear some five to eight months after birth, or even later. It is now believed that the changes in the skeleton of cretins are due to delayed ossification of the cartilages. Hofmeister (*Fortschritte auf dem Gebiete der Roentgen-Strahlen*, Bd. i., Hft. i., 1897), studying a case of cretinism with the *x*-rays, found that the epiphyseal ends of the bones grew slowly, and that the epiphyseal plates persisted for a long time. The bones were small. Ossification may in time be completed, but the process may take years; in fact, cretins may continue to grow until they are thirty or forty years of age. Periosteal osteogenesis is normal, or may be in excess. The peculiar appearance of the nose is due to premature synostosis of the bones at the base of the skull, although, as Niepce, Stahl, and Klebs have shown, this anomaly of bone formation does not always occur.

The stunted growth is believed by Bircher (*loc. cit.*) to be due to defective development of the cartilage cells, as was found occasionally by Virchow and Klebs at the base of the skull. We find, therefore, that cretinism and the so-called chondrodystrophia have much in common. The resemblance can, however, be made out clearly only in the case of chondrodystrophia of Kaufmann's first group. Cretinoid chondrodystrophia might be explained as cretinism that had become marked at a very early period of intra-uterine life.

Further information might be obtained by an inquiry into the condition of the thyroid gland in chondrodystrophia. Hofmeister ("Experimentelle Untersuchungen über die Folgen des Schilddrüsenverlustes," *Beiträge zur klin. Chirurgie*, 1894) holds that the changes in the bones produced by thyroidectomizing rabbits are identical with those found in chondrodystrophia as described by Kaufmann, H. Müller, Kirchberg, and Marchand. Although we must admit the great similarity of the lesions in the two cases, this, of course, does not prove identity. Leblanc (Comptes rend. de Soc. de Biol., 1902, liv., 88–89) states that chondrodystrophia is often associated with myxœdema and that disturbance of the thyroid is the causa morbi. Nasan (*Rév. de Neurologie*, 1901, p. 549) is of the same opinion. There is no need of entering here into the question of the identity of myxœdema and

cretinism, further than to say that it is proved practically beyond doubt that the two are one and the same thing, and due to defect in the function of the thyroid. Any differences are to be explained in respect to the time at which the athyroidea first makes itself manifest. Myxœdema is cretinism manifesting itself in the adult; cretinism is myxœdema of childhood. In opposition to the views of Leblanc and Nasan may be cited the experience of Cestan ("Nouvelle Iconographie de la Salpêtrière," 1901, xiv. 277), who found a condition of chondrodystrophy in a girl nine and a half years old, unimproved by thyroid feeding for nine months, and of Marie (*Presse médicale*, Juillet, 1900, vol. iv.), who in two cases found no benefit from the use of thyroid extract. We should observe, too, that the lesions of chondrodystrophia are said to develop in the earliest period of fœtal life before the thyroid is properly formed.

With regard to the anatomical peculiarities of the thyroid in chondrodystrophia it is not always possible to obtain accurate information. So far as I have been able to trace them they will be found in the preceding table.

Unfortunately, not having access to the original papers in all instances, I am not able to give complete information in the above table, and the number of cases might be added to. We see, however, that out of twenty-nine cases the thyroid is abnormal in eight, either absent, atrophied, or hypertrophied. And it is further striking that in all the cases in which the thyroid is obviously diseased, with one exception, the clinical type has been cretinoid; with, in two cases, some additional features resembling myxœdema. The one exception, Hektoen's case, is probably to be explained on the ground of a compensatory action of the hypophysis, which was considerably enlarged, but otherwise of normal structure. In Bowlby's case, which is recorded as a case of cretinism, being observed before the distinctions between the different forms of abnormal osteogenesis were so closely drawn as they are at present, the skin was œdematous and semitranslucent, the nose was broad and flat, and there were no eyelashes or eyebrows. In Salvetti's case the skin was also œdematous. In the one case in which vascular struma is stated to have been present (Scholz), there were apparently no signs of cretinism; but this anatomical condition of the thyroid does not of course imply deficiency of the secretion; rather is it akin to what is found in exophthalmic goitre or hyperthyroidism. This association of defective thyroid secretion, which must be admitted where the thyroid structure is so extremely altered, with the cretinoid type of Kaufmann's chondrodystrophia can hardly be fortuitous, especially when we note that in the cases that are distinctly without cretinoid features, the thyroid has been, so far as we can judge from the imperfect information that we are given, practically normal. In settling this latter point we can admit as conclusive evidence only cases that have been controlled by post-mortem examination. Still, the position is supported to some extent by clinical cases. It is, it must be remarked, difficult to draw conclusions as to the functional efficacy of the thyroid from an estimate of its size alone derived from palpation. Osler (Trans. Congr. Amer. Phys. and Surg., 1897, vol. iv., pp. 190–192) describes two cases of chondrodystrophia in French-Canadian children, who did not present the cretinoid facies, in whom the thyroid was not enlarged on palpation. Joachimsthal (*Deut. med. Woch.*, 1899, S. 288) also reports a case of chondrodystrophia hyperplastica, without the cretinoid appearance, in which also the thyroid was normal on palpation. As corroborative evidence, also, it may be noted that Virchow (*Virch. Archiv*, 1883, xciv., S. 183), in the canton of Glarus, Switzerland, where goitrous cretinism is endemic, found not a few cases of chondrodystrophic dwarfism without the gross signs of cretinism. It would seem, so far as we can judge from so limited a number of observations, that the cretinoid type of chondrodystrophia, as described, is simply a form of cretinism, or at least due to thyroid inadequacy. If this be the case, it then follows that Kaufmann's chondrodystrophia fœtalis is probably not a distinct disease entity, but that several differing conditions are included under the one name. Some stress has been laid on the peculiar retraction of the root of the nose, which is so evident a feature in typical cretinism, as an aid in the diagnosis of these conditions. It should be said that this feature is not always present in undoubted cretinism and, moreover, the explanation given of it, namely, that it is due to premature synostosis of the os tribasilare, does not invariably hold good. Some of Kaufmann's cases show that retraction of the root of the nose may be present without premature ossification of the os tribasilare. In these exceptions he attributes the appearance to shortening of the bony parts in front of the os. Conversely, the synostosis may take place without producing any effect on the condition of the nose. Consequently too much weight should not be laid on this point.

It would, perhaps, be also premature to conclude that the other forms of chondrodystrophia may not be dependent on thyroid dystrophy. It is true that Cestan, Marie, and Christopher have failed to get benefit from thyroid feeding in chondrodystrophia. As the disease, however, originates during intra-uterine life, by the time the cases come to observation the main damage has been done, and it is not to be expected that any form of medication would have a marked effect on bony structures once they were formed. The only possible chance would be if the cases could be treated from birth; but, so far as I am aware, this has not been done. This fact weakens the therapeutic argument very much. Further, it does not follow that because the thyroid is of normal size and appearance that it is competent to perform its function. While an absolute deficiency in the amount of secretion furnished by the thyroid will undoubtedly produce the symptoms that constitute cretinism or myxœdema, it is quite possible that a relative inadequacy will produce the same symptoms. This aspect of the case, which has been emphasized by Prof. J. G. Adami ("Internal Secretions Considered in their Physiological, Pathological, and Clinical Aspects," Trans. Congr. Amer. Phys. and Surg., vol. iv., 1897) has been constantly overlooked by writers on the subject. The doctrine of internal secretions supposes the existence of some substance, the product of metabolism, for the secretion to act upon. The thyroid, therefore, may be normal, but if the substance upon which it acts is produced in excess, then the gland will be insufficient for its work, and the various symptoms of athyroidea may make their appearance. In some few instances in which the hypophysis has been invaded by a tumor, symptoms of myxœdema have occurred with an intact thyroid, the thyroid and the hypophysis being, as is now well recognized, more or less complementary organs. Relative inadequacy of the thyroid—and, *mutatis mutandis*, the same remark applies to the hypophysis and other glands furnishing an internal secretion—is a factor that can by no means be neglected in these obscure disorders of development. Until, however, we know much more about the nature, chemical and otherwise, of metabolic processes, we must leave such questions to the realm of speculation.

In concluding, we should not forget to say a word or two in regard to the relationship between anomalies in structure and function of the genital tract and the general question of somatic development. It is a matter of common knowledge that the changes in the genital organs which occur at puberty are coincident with an increased nutritional and functional activity of the body as a whole, as is evidenced by the rapid growth, the consolidation of the figure, the production of hair, the deposit of fat, the changes in the voice, and the altered mental characteristics, all of which together constitute the adult type. Certain isolated facts bring this relationship into still greater prominence. Genital hypoplasia, with its associated sexual torpidity, amenorrhœa, and even sterility, has been found in certain dwarfs, in myxœdema and cretinism, in acromegaly, and in some forms of gigantism. This would suggest that there is some functional relationship between the thyroid gland, the pituitary body, and the genital organs. The almost constant genital insufficiency found in conditions of athyroidea is so well recognized that I need not do more than mention it. That a similar peculiarity may be associated with lesions of the pituitary body is perhaps not so widely known. Some years ago I performed an autopsy on a female about thirty years of age, who died with symptoms of a basal tumor of the brain. The genitalia were markedly infantile in size and appearance. A tumor of the hypophysis was found, although there were no signs of acromegaly. A similar case is one reported by Babinski (Society of Neurology, June 7th, 1900), who found signs of infantilism, viz., lack of body hair, amenorrhœa, an excess of fat, in a girl of seventeen, but without acromegaly, who post mortem exhibited a tumor of the pituitary. Analogous peculiarities have been found in the male in such cases. While it is true that children the subjects of atrophy of the genitals are often small, instances of the reverse are not unknown. Eunuchs are often of more than normal height. The increase in length is most manifest in the lower limbs, a peculiarity that is to be observed also in the capon, or castrated chicken, and in the ox. The relationships suggested by the above observations might be depicted graphically in the diagram (Fig. 5124).

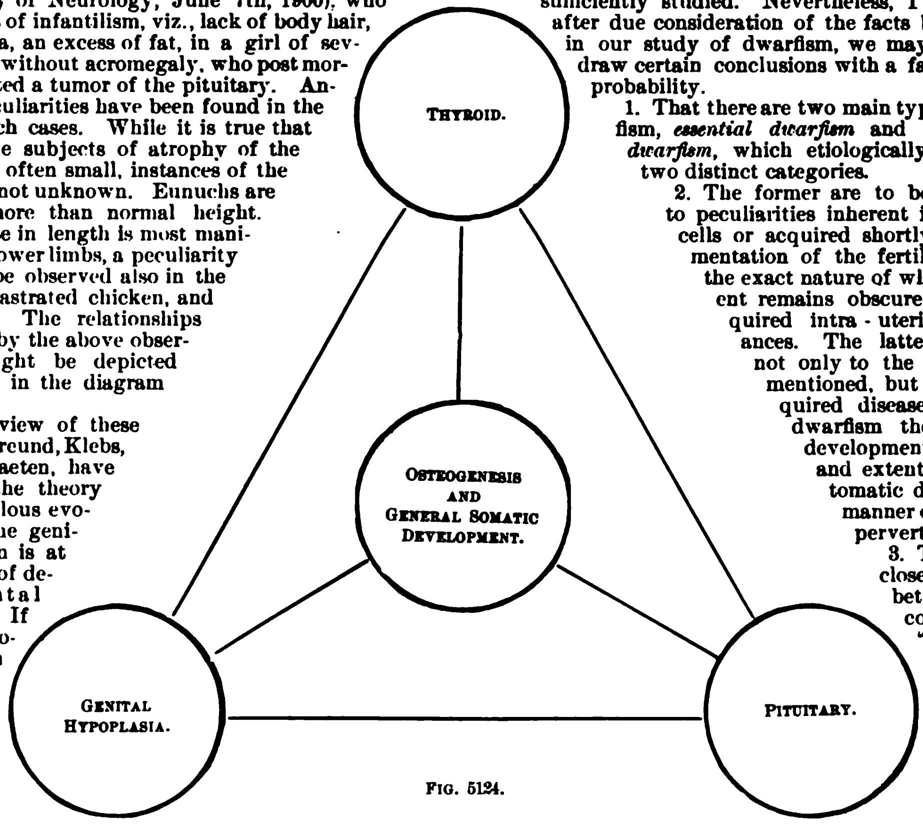

Fig. 5124.

It is in view of these facts that Freund, Klebs, and Verstraeten, have advanced the theory that anomalous evolution of the genital function is at the bottom of developmental dystrophy. If genital evolution be in excess, gigantism or acromegaly will occur; if defective, infantilism or dwarfism results. It seems to me, however, that this is much too strong an assertion, and one that is not supported by the facts, as we know them. Such a theory supposes the existence of an internal secretion in the case of the genital organs, to wit, the testes and ovaries, the evidence for which is not beyond question. Further, the association between genital anomalies and developmental peculiarities is not necessarily direct, as cause and effect, but may be indirect through some third factor. We have experimental evidence to show that defect of the thyroid will produce hypoplasia of the genitalia, but not the converse, and in this case as a matter of fact genital hypoplasia is simply part and parcel of a systemic developmental defect. In the case of the pituitary evidence is scanty, inasmuch as experimentation, except in the single particular of pituitary feeding, is extremely difficult. The evidence, so far as I can gather it from autopsies, seems to favor the view that certain lesions of the pituitary, provided they arise early enough, may prevent the proper development of the genital organs. There is absolutely no evidence to prove that hypoplasia or any other pathological condition of the genitalia has produced disease of the pituitary. Could it do so, one would suppose that, considering the very respectable number of cases of aplasia and hypoplasia of the genital organs that have been described, some abnormality of the pituitary body would occasionally have been noted. This is, however, not the case. It would seem more probable that genital hypoplasia, if not indeed always an effect, is an associated condition merely. In regard to the factors at work in this very interesting but obscure condition of anomalous development, the sum and substance of the whole matter is that our views cannot attain finality until we know much more of the chemistry of the internal secretions and of metabolic processes generally. Hitherto the anatomical peculiarities and the pathological chemistry of the thyroid and pituitary glands in cases of dwarfism and giantism have not been sufficiently studied. Nevertheless, I think that after due consideration of the facts brought out in our study of dwarfism, we may be able to draw certain conclusions with a fair degree of probability.

1. That there are two main types of dwarfism, *essential dwarfism* and *symptomatic dwarfism*, which etiologically belong to two distinct categories.

2. The former are to be attributed to peculiarities inherent in the germ cells or acquired shortly after segmentation of the fertilized ovum, the exact nature of which at present remains obscure, or to acquired intra-uterine disturbances. The latter are due, not only to the causes just mentioned, but also to acquired disease. In true dwarfism the defect of development is in time and extent; in symptomatic dwarfism the manner of growth is perverted as well.

3. There is a close association between such conditions as "fœtal rickets," cretinism, osteopsathyrosis, osteoporosis, osteogenesis imperfecta.

4. Fœtal rickets so called has nothing to do with rickets as it is ordinarily understood.

5. The term *chondrodystrophia fœtalis* is a misnomer, inasmuch as it implies a local lesion, and, moreover, attributes it to a nutritive cause, whereas not only the cartilage but the bone and soft tissues are involved. Virchow is probably correct in regarding it rather as a developmental anomaly.

6. The three types, chondrodystrophia hyperplastica, chondrodystrophia hypoplastica, and chondrodystrophia malacica, are probably not varieties of the same disease.

7. Chondrodystrophia of Kaufmann's first or cretinoid type is probably a modified cretinism.

Albert George Nicholls.

EMBALMING.—This article is intended to furnish useful information to the medical practitioner who may be called upon to preserve a dead body for a limited period of time. This duty can occur only when it is not possible to secure the services of the professional embalmer.

When the object in view is simply to keep the dead human body from undergoing decomposition for a few days, there are a number of methods from which the physician may make a choice. Thus, for example, when it is possible to obtain ice in plenty and the services of a person who can be trusted to renew the supply as frequently as may seem desirable, this method of preventing or at least postponing decomposition is probably as good as any other that can be suggested. But it is often impossible to obtain ice in the desired quantity, or the period of time during which the dead body must be preserved is longer than is compatible with the employment of this method. Under these circumstances it becomes necessary to fall back upon some other procedure, one, for example, which depends for its efficacy upon the employment of chemical reagents. Among the large number of such procedures the physician may be compelled, by reason of the circumstances in which he happens to be placed, to select one of the simpler and less efficacious methods. I will therefore mention a few of these first, reserving to the last an account of the steps which one must take if it be desired to preserve the dead body in good condition for a reasonably long period of time—for months or even years. It is only to such a procedure that the term embalming may with propriety be applied.

Methods Suited to the Preservation of a Dead Body for a Short Period of Time.—(*a*) Place the body, without opening it, and as soon as possible after death, in sawdust mixed with powdered zinc sulphate. The skin, it must be remembered, has a tendency, under continued exposure to this reagent, to assume a yellow color.

(*b*) Open and clean the body and viscera, and keep all the parts that can be reached saturated with a corrosive sublimate solution (1 in 1,000) or a formalin mixture (of a strength of from five to ten per cent.). Cloths saturated with the same fluid should be wrapped around the body, and enough of the preservative should be added from time to time to keep the cloths constantly moist.

(*c*) Open a femoral artery at the apex of Scarpa's triangle and inject a solution of arsenous acid (eight drachms in 9 kgm. of alcohol; cinnabar, q. s.). Then open the abdominal cavity, wash out the cavities of the stomach, bladder, and intestines, and inject the preservative solution into them freely.

(*d*) Camphor dissolved in alcohol, in the proportion of 1 part of the former to 6 of the latter, can be used effectively as a preservative fluid. Another mixture is the following: Oil of turpentine, 5 pints; Venice turpentine, 1 pint; oil of lavender, 2 ounces; oil of rosemary, 2 ounces; vermilion, q. s.

Another mixture, which has been used with some measure of success in England, is the following:—To one pint and a half of glycerin add three quarters of a pound of white arsenic (arsenous acid) and boil; afterward add one gallon of pure glycerin. Still another useful mixture is one composed of alcohol and glycerin in equal parts (each representing forty-seven and a half per cent. of the entire bulk), and carbolic acid to the extent of five per cent. A small quantity of arsenic (about one per cent.) may, if desired, be added to the mixture.

All of the ingredients mentioned in the preceding paragraphs are, as a rule, easily obtainable, and the manipulations required call for no special skill. At the same time it must be remembered that these procedures can at best retard decomposition for only a relatively short time. Thoroughly satisfactory results can be obtained only through the more elaborate and painstaking methods adopted by the professional embalmer.

An Effective Method of Embalming.—Mr. Frank E. Campbell, of 241 West Twenty-third Street, New York City, a recognized authority in embalming, has very kindly allowed the use of the following description of the method of embalming which he prefers:

"I. Bathe and dress (in underclothing) the body to be embalmed, and place it upon a board supported in an inclined position. Close the mouth and eyes, and securely plug all orifices.

"II. Place within easy reach all the instruments and various objects that will be needed, viz., scalpel, aneurism needle, blunt hook, scissors, arterial tube, five six-inch lengths of linen thread for tying about the vein and artery when raised, a threaded needle suitable for sewing up incisions, a bulb syringe, a large bottle filled with the embalming fluid, a sponge, a supply of cotton, etc. Sink the suction end of the tubing of the bulb syringe into the embalming fluid contained in the bottle and squeeze the bulb several times in order both to fill it with the fluid and to force out the air which it contains. When these objects have been accomplished the discharge end of the syringe should also be introduced into the bottle, in order that no leaking may take place.

"III. Connect the aspirating pump, by means of tubing and a gooseneck, with an empty aspirating bottle suitable for holding the blood to be withdrawn from the body. Then attach to the free end of the tubing a long silk-covered vein tube, or, better still, a flexible wire catheter.

"IV. Expose the femoral vessels in Scarpa's triangle over an area two or three inches in length and dissect them clean. Then, with one of the lengths of thread already prepared, tie the artery at the lowest possible point with a firm knot, for the injection is to be made only in an upward direction.

"V. Next, pick up the vein and treat it in the same manner as the artery, remembering, however, that the structure of the vein is fragile and that it may easily be punctured or torn. Make a slit, about a quarter of an inch long, lengthwise in the vein. As blood will escape from the vessel when it is thus opened, it is well to prevent this by making pressure upon the vein with the finger or with a blunt hook. Insert the vein tube into the opening in the vein and push it upward to or near the right auricle of the heart. Pass a piece of the thread snugly, but not too tightly, around both vein and tube, and tie it with a simple knot. Attach the tubing of the aspirating pump and begin to pump the air from the bottle. When the air has been withdrawn from the bottle, the vacuum will draw the blood from the body by way of the vein tube. If no blood flows into the bottle after the air is pumped out, it may be assumed that a clot of blood has probably entered the free end of the tube in the vein, or else that there was no blood at the point where the end of the tube rested. Draw the tube slowly downward, and, if there is still no flow of blood, push the tube as far back into the vein as it will go, detach the rubber tubing from it, and, by means of the bulb syringe, inject a bulbful of aqua ammoniæ, for the purpose of dissolving the clotted blood. After this has been done, resume the operation of aspirating. When all the blood that can possibly be removed in this manner has been aspirated, withdraw the tube for about one-third its length, and let it remain in the vein. (Always keep a vacuum in the bottle.)

"VI. Next, pick up the artery, slit it, and insert the arterial tube with care. Then pass the remaining piece of thread around it as far up as you can, and tie it with a simple knot. Attach the bulb syringe (previously made ready) to the tube and begin the injection slowly. When about one-third of a quart of the preservative fluid has been injected, stop and begin once more to aspirate the vein, for by this time the fluid injected into the artery is forcing the blood ahead of it, and the blood will flow again more freely.

"VII. Administer the injections and the aspirations in alternation until a quantity of the preservative fluid varying from three pints to five or six pints, according to the size of the body, shall have been injected, and also until a clear fluid, and not a bloody one, escapes from the vein tube as a result of the aspiration. Any discolorations of the face, ears, or neck, will probably by this time have disappeared. If it should be found, however, that a slight discoloration still remains in the lower part of the ears, or in the neck, a slight rubbing will in most cases remove it.

"VIII. After it is seen that only clear fluid flows into the blood bottle, draw out the vein tube and tie the vein tightly.

"IX. Continue the injection of fluid into the artery until the veins of the temple, the large vein on the forehead, and the jugular vein, as well as the veins in the arms and hands, indicate that they are filled. Then remove the arterial tube and tie the artery tightly with the same thread that held the tube in place. Pack the wound well with moist 'lintine,' and sew up the incision with the 'baseball' stitch, drawing the edges snugly together.

"The arterial work is now completed.

"X. For successful work on the cavities of the body there will be needed a twelve-inch trocar, an instrument that will reach every point where it is desirable to apply the preservative fluid. At the same time it must be remembered that much damage can be done with a trocar of these proportions if it be not used with care. It is therefore important to avoid injuring the trunks of arteries and veins, and the various organs.

"Insert the trocar just far enough to penetrate the abdominal wall, and connect it with the aspirating pump. Draw the gases and liquids through it into the empty bottles. Through his knowledge of the anatomical relations of the different organs the physician should be able, without removing the trocar from the opening in the abdominal wall, to carry out successfully the following procedures: He should puncture the stomach and draw from it all the gases and liquid contents, and then, after he has accomplished this, and without removing the trocar, he should inject two bulbfuls of the embalming fluid into the cavity of this organ. The aspirator should then be re-attached to the trocar and the latter should be made to pierce the intestines, both the large and the small. In this way it will be possible to remove any gases or fluids which these organs may contain. The bladder should be treated in the same manner. Never puncture the liver, as it cannot be aspirated or injected, and the original arterial injection may be trusted to preserve it from decomposition. As a final step connect the trocar with the syringe and copiously flood the intestines with the preservative fluid.

"Where death occurs from pulmonary tuberculosis or from pneumonia, turn the point of the trocar upward toward the lungs and cause it to penetrate into the thoracic cavity as far as it will reach. Aspirate first from one pleural cavity—for example, the right—and then from the other; care being taken, after the aspiration of the first pleural cavity, to withdraw the trocar well into the abdominal cavity before the attempt is made to push it on into the second. When both pleural cavities have been thoroughly aspirated, flood each of them with embalming fluid in a cautious manner and then withdraw the trocar altogether.

"With needle and thread close the opening in the abdomen by means of a drawstring suture. Pack the nose with lintine thoroughly moistened with embalming fluid, and pack the rectum and vagina in the same manner. The embalming will then be completed."

While Mr. Campbell does not state which particular preservative mixture he considers the best, it is fair to assume that sufficiently good results may be obtained by the employment of any one of the half-dozen or more standard embalming fluids which are offered for sale in the shops. *William Sohier Bryant.*

EMPHYSEMA, SUBCUTANEOUS.—By this term, or pneumatosis, is meant the presence of air or other gaseous compounds beneath the skin.

The resultant SYMPTOMS are these: a swelling covered with skin of either normal appearance or, if the pressure upon it be great, rather pale; this tumor pits upon pressure, as in the case of anasarca, but the pitting more quickly disappears when the swelling is due to the presence of air. Palpation causes a peculiar crackling or crepitation in the subcutaneous tissues. If the air have entered from without, a wound or puncture can generally be discovered; if from within, expiratory efforts with closed lips and nostrils will generally produce immediate increase in size. It is possible for the whole subcutaneous tissue to become inflated from any superficial part of the body as a starting-point.

In case the emphysema is that of decomposition, there may be an altered hue of the integument; but the discoloration, of course, is entirely independent of the emphysema.

Subcutaneous emphysema may result from causes either traumatic or pathological. Among instances of the latter may be mentioned ulcers or abscesses communicating with the air passages, and, as already suggested, gangrene.

We may include in the discussion of this subject emphysema of other parts external to the lungs, such as mediastinal and submucous collections of air.

In the *head*, orbital emphysema sometimes follows a blow of sufficient violence to break one of the thin and fragile bones of the inner wall of the orbit—the lachrymal or the orbital plate of the ethmoid. If, soon thereafter, the patient blows his nose, the compressed air finds a ready exit from the nose into the orbit, and distends the lids.

Eustachian emphysema: here an ulcer of the tube, or a rupture following awkward Eustachian catheterization, has led to distention and approximation of the pharyngeal walls by the dissecting air. Blowing the nose and the Valsalvian experiment increase the emphysema in these cases. Von Tröltsch[1] mentions a case, within his own experience, in which dysphagia consequent upon such emphysema persisted for five days.

In the *neck* we may have escape of air as a result of foreign bodies, ulcers, or abscesses perforating the œsophageal, laryngeal, or tracheal wall; but emphysema will not be produced if, as a result of the perforation, a broncho-œsophageal fistula be established.

Ulcers of the larynx or trachea may lead to submucous dissection by air. Wounds of the neck penetrating these parts may be followed by subcutaneous emphysema if there is not free escape for the expired air. Under these circumstances inflation of the skin has been known to occur over an area extending from the head to the scrotum.[2]

As a rule, the consequences are not serious; but Holmes[3] quotes Hilton as stating that emphysema about the phrenic nerves may so interfere with their functional integrity as to cause death.

During tracheotomy, and afterward if much inspiratory difficulty be present, Champneys[4] finds that anterior mediastinal emphysema, and even pneumothorax, are liable to occur; and this is especially so if artificial respiration by Schultze's method be employed.

In the *chest* we may have the surgical symptom in question produced in several ways. Pathologically, as by the opening of a vomica or abscess of the lung into the parietes of the chest, the two pleural surfaces being adherent at the point where the abscess perforates. (If the parts were not adherent at this point, there would, of course, simply be a peumo- or a pyopneumothorax.) Emphysema sometimes complicates wounds of the chest-wall, both the penetrating and the non-penetrating varieties. In the latter instance, the air which enters the wound from without during one movement of respiration is prevented in a valvular way from escaping during the opposed movement, and is disseminated by the muscular and tegumentary pressure upon it during this movement. In the case of wounds penetrating the parietal pleura only, we may, besides the consequent pneumothorax, have a subcutaneous emphysema from the same reason.

Wounds that penetrate the lung, and a puncture of the lung by a fractured rib, are alike liable to produce emphysema, air escaping from the lung with the same result as in the case last given.

An additional and rare variety of traumatic emphysema of thoracic origin is that consequent upon rupture of air cells by violent expiratory efforts, with a closed or partially closed glottis, as while coughing, straining, or blowing a wind instrument. Here the air makes its way between the lobules, and, unless it ruptures the pleura, producing pneumothorax, it escapes at the root of the lung into the mediastina, and thence into the cellular tissue of the neck, becoming subcutaneous.

Guttman[5] says: "Most of the cases of this variety of emphysema are observed in connection with croup, diphtheritis of the larynx, whooping-cough, and bronchitis in children, and with advanced pulmonary emphysema in the aged."

In 1884 I met with the only case which, as yet, I have found complicating whooping-cough. The patient, a child of two years, had been suffering for about three weeks, the parents said, from violent fits of coughing. I was called to treat the sudden appearance of "dropsy" in the case. I found the skin of the head, neck, and chest distended, crepitation everywhere well marked, and no dropsy. Whenever the child coughed the swelling increased in size suddenly, apparently causing distention first in the left supraclavicular region. The respiration was rapid, but seemingly free; the pulse rapid and feeble. The child died within a few hours. Unfortunately, no autopsy was allowed.

In the *abdomen* we may have subcutaneous emphysema from ulcerative perforation of the stomach or intestine at a point previously adherent to the abdominal wall. Unless such adhesions prevent it, gas will escape from the viscera into the peritoneal cavity.

TREATMENT.—As a rule, air beneath the skin is of slight consequence and requires no treatment, becoming absorbed after a time. If, however, important parts—as the phrenic nerves, or the larynx, trachea, etc.—are subjected to a degree of pressure injurious to respiration, or if the subcutaneous air is spreading further and further, we may employ pressure at the point of escape, or may make incisions through the skin to give relief to tension, or both.

Subcutaneous emphysema possesses an interest for us outside of its pathological or accidental causation. It has often been induced intentionally by the malingerer; and, moreover, its production has been seriously advocated by Dr. H. R. Sylvester[6] in an article entitled "On Life-saving from Drowning, by Self-inflation." Here it is recommended that those in peril of the deep shall make a small puncture or cut in the cheek, leading *from* the mucous membrane about opposite the first molar *to*—but not through—the superficial fascia and skin; and then, closing the lips tightly, they shall proceed to blow themselves up, until the skin of the head, neck, and chest is distended. Dr. Sylvester alleges that a moderate and quite painless and harmless inflation is ample to keep one afloat without effort.

It seems probable that Vidocq refers to such a practice when, in his memoirs—as mentioned by Gavin,[7]—he asserts that he could make his head swell like a bushel, without giving pain, and that he could remove all traces of it by the day following.

In order to test the degree of pain, and the subjective effects of such distention upon the skin, I some time ago performed the following experiment, assisted by my friend Dr. F. A. Manning: Having connected, by a piece of rubber tubing, a hypodermic needle with my compressed-air receiver, I forced air beneath the skin of my left forearm until the limb was much increased in size, the skin tense, and emphysematous crepitation could be felt from wrist to armpit. The pain was very trifling in amount. The distended skin was somewhat anæsthetic; whereas before the injection I could distinguish separate points on the anterior surface at an average distance of 4 mm., immediately thereafter I could name them only when they were 10–15 mm. apart. Still, pinching and pricking were distinctly painful. The emphysema thus induced was slow in disappearing. It was still somewhat noticeable on the third day after the experiment.

As regards the production of emphysema upon the human subject with intent to deceive, it has been employed to simulate hernia, hydrocele, hydrocephalus, ascites, etc. Gavin (*op. cit.*, p. 389) says: "It is a trick used every day by butchers, and has been known from time immemorial by the Ethiopians and mendicants of Abyssinia." Beck[8] quotes Sauvage's "Nosology" regarding a mendicant who "gave his child all the appearances of hydrocephalus by blowing air under the tegument of the head near the vertex." He also cites a case of emphysema of the abdominal parietes, induced by a woman who wished to feign dropsy.

Sir George Ballingall[9] declares that the artificial production of this for the simulation of other diseases is regulated by a recipe current in the British army.

The differential diagnosis of the tumors so caused presents no difficulty. *Robert H. M. Dawbarn.*

ENTEROPTOSIS.—(Synonyms: Glénard's Disease, Splanchnoptosis [Stiller].)

INTRODUCTORY AND HISTORICAL.—Anomalous downward displacements of the abdominal viscera were described by Virchow, Leube, and others, several years before Glénard's monograph appeared. In this article, which was published in 1885, Glénard set forth his views upon enteroptosis and connected therewith certain nervous phenomena which have since borne the name of "Glénard's disease." Prominent among the features of this symptom complex, which Treves is pleased to call "that medley of symptoms," are downward displacement of the stomach, a movable right kidney, various digestive disturbances, and often very typical neurasthenic symptoms.

The interest thus awakened in postural anomalies of abdominal organs by Glénard's article is as keen to-day as it was eighteen years ago, and many physicians have verified the statement of that author which he made with such enthusiastic earnestness at the close of his early monograph. "I can affirm," wrote Glénard, "that the physician who will follow my directions and strive to verify my statements in such cases will find in his practice the satisfaction which a positive diagnosis gives to both physician and patient, from which alone a proper prognosis can be made, and that satisfaction, the greatest of all, which directs the treatment and avoids for the patient the trial upon him of so many remedies, while at the same time it secures him relief and prevents the physician himself from falling into therapeutic scepticism."

The investigations made by the French were rapidly followed by similar work among the German clinicians, with the result that another view of the cause of the displacements was advanced. Then the English and American writers contributed articles and case reports upon the subject, dealing with the nature and anatomy as well as with the etiology and treatment of the disease. One cannot close this introductory historic note without mentioning the fact that the lectures of Arthur Keith on the nature and anatomy of Glénard's disease comprise one of the best studies upon this phase of the question yet published and will be duly recognized later in this article.

The application of the term Enteroptosis.—It would appear that Glénard's original article included a description of a displacement of the intestines alone. The Germans broadened the application of the term and made it to include, in most instances at least, ptosis of all the abdominal viscera. Schwerdt, however, pleaded that the term was applicable when at least two of these organs suffered downward dislocation. If, on the other hand, one would wish to be specific, the organs so displaced might be specified by *gastroptosis*, for instance, or *nephroptosis*, and so on.

ETIOLOGY.—The study of visceral ptosis, from the etiologic standpoint, has provoked a variety of theories differing so widely that it is manifestly impossible to find one theory broad enough to explain all cases. It has been urged that enteroptosis is a congenital anomaly (Stiller); that it is a constitutional ailment (Schwerdt), a general atony of nervous system and muscles; that it is the result of wearing corsets, or tight waistbands with heavy skirts (Meinert); that it is a result of a neurasthenia basis (Charcot); that rapid emaciation or a severe illness may account for it; that to overlifting or frequent pregnancies many cases may be traced; that adhesions, the result of peritoneal inflammation, may pull down one organ after another (Treves); that it is a reversion to a fœtal or an embryonic type (Rosengart); and the latest, and by no means the least ably supported theory, is that which would regard enteroptosis as "a result of a vitiated method of respiration," and assign it to a place among respiratory diseases (Arthur Keith).

It is admitted, we believe, that there are several factors which maintain the various abdominal organs in position, and of these the most important are: (1) The intra-abdominal pressure, and (2) the ligamentous attachments of the viscera to the body walls. These two are so important that when either fails ptosis may result. Hence it may be said that these factors are those by which the normal postural relations of the viscera are maintained. It is not difficult then to believe that any cause, or number of causes, which lowers the intra-abdominal pressure by exhausting the muscular tone, or which weakens or stretches the supporting ligaments, would readily alter the relation of the organs—especially of the heaviest organs or of those with weakest supports—and result in ptosis.

Thus, as one reviews the various etiologic factors suggested above, one finds most of them—perchance all of them—applicable to a large number of cases. The last theory suggested, however, "enteroptosis as a result of a vitiated method of respiration," certainly requires some explanation. When Dr. A. Keith remarks that enteroptosis is a result of a vitiated method of respiration, he means, doubtless, that faulty movements of the diaphragm, resulting from a variety of causes, determine visceral ptosis, and that whereas under normal relations of the muscles of inspiration—the diaphragm, the external intercostals, and the interchondrals—to the muscles of expiration, and chiefly those of the abdominal walls, there is but slight downward displacement of the viscera. The organs swing and move upon each other, often as much forward as downward, maintaining their normal positions and postural relations. As a result of various conditions the inspiration muscles may "gain the upper hand and the muscles of expiration yield," and ptosis is induced. This writer strongly emphasizes the importance of the diaphragm in bringing about the changes incident to enteroptosis. He remarks that the inspiratory downward displacement, if once the diaphragmatic supports commence to yield, is one of the factors in the causation of visceral ptosis; and while minimizing the function of visceral bonds in the causation or prevention of enteroptosis, he maintains that the active contraction of the crura is the most important factor in the production of visceral ptosis, acknowledging in the same article that while the supports of the diaphragm are threefold—abdominal, costal, and thoracic—doubtless that derived from the abdominal muscles, the muscles of expiration, is of the most importance.

At all events, one is justified in ascribing highest importance to the action of these muscles, since it appears that the normal respiratory swing of the organs, the stomach, liver, and spleen, gives place to downward displacement in the presence of relaxation of the abdominal support, or what is even worse, perhaps, when the body cavity is constricted by corsets or distorted by disease, the action of the diaphragm pushes the organs down. Corsets when applied prevent an inspiratory downward displacement of the liver, but when removed the relaxed condition of the muscles—being too weak to oppose the dropping—favors ptosis.

"The condition essential to the displacement of either kidney is a diminution of the subdiaphragmatic space which may be accounted for, (1) by compression of the thorax with clothing, (2) by a partial collapse of the thoracic walls, following chest or spinal disease, and (3) by the permanent contraction of the diaphragm, which follows a relaxed or paretic condition of the abdominal walls." The left kidney is not displaced so frequently as the right, from the fact that "the left hypochondrium is provided with a safety valve in the shape of the splenic flexure of the colon." So that when the subdiaphragmatic space is lessened, the "colon is extruded and the other organs are left undisturbed." Again, the close attachments of kidney to spleen, and of spleen to diaphragm, prevent dislocation. From the domain of comparative anatomy one may gather some clew also to this condition. It is affirmed that with the evolution of the orthograde posture and the orthograde type of respiration, mesenteric adhesions, which appeared one after the other in five different areas, spread out and bound the alimentary tract more and more to the abdominal wall as the animal became more and more orthograde in posture. Hence, various degrees of extent and strength of mesenteric adhesions due to arrest of development or otherwise, may help to account for visceral ptosis, in some instances at least.

Whatever the active causes may be which bring about enteroptosis, it may be said that the intra-abdominal pressure is lowered, the organs may be pulled down, and there is more than a mere probability that a congenital predisposition exists in the character of the supporting tissues of the organs, whether these be ligaments or muscles, or both.

CLINICAL FEATURES.

SYMPTOMS.—Enteroptosis does not invariably give rise to symptoms, or, in other words, a considerable degree of downward displacement of one or more of the abdominal organs may exist without calling forth any complaints. On the other hand, however, whether as a result or not cannot always be established, one finds a variety of symptoms referable to the digestive tract, the nervous system, the condition of the blood, and so on; in a word, all manner of subjective symptoms may exist, from the severest abdominal pain, usually spasmodic, to the mildest paræsthesia.

It must be admitted, however, that, prominent and more frequent among the complaints urged by the subjects of enteroptosis, are those of digestive disturbances—distressful weight after food, referred to the right upper quadrant; sometimes spasmodic pain; sometimes vomiting, flatulence, constipation, and throbbing in the abdomen. The distress, which in pronounced cases is for the most part constant and referred to the upper quad-

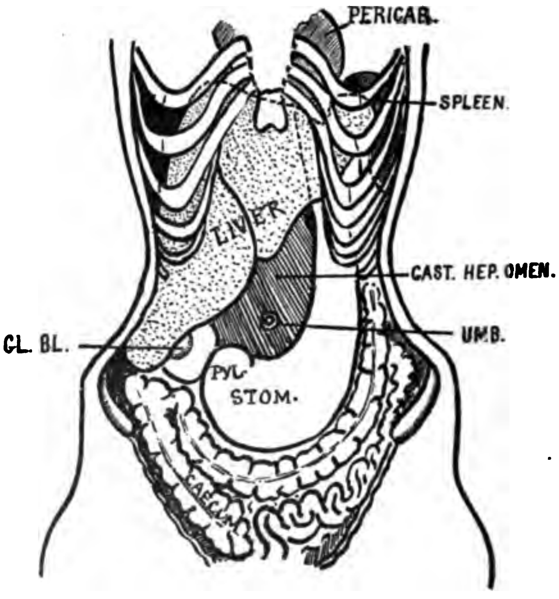

FIG. 5125.—Partial Ptosis of the Viscera in a Woman Aged Forty-five Years. The duodenum descended as far as the brim of the pelvis. (Keith.)

rants, is promptly relieved on assuming the horizontal position, only to return again on getting up and walking about. Hence some persons make this complaint prominent while speaking of their symptoms. It is interesting, in this connection, to note that constipation, which in one case under the writer's observation was very obstinate, at different periods always disappeared when the patient lay in bed for a few days.

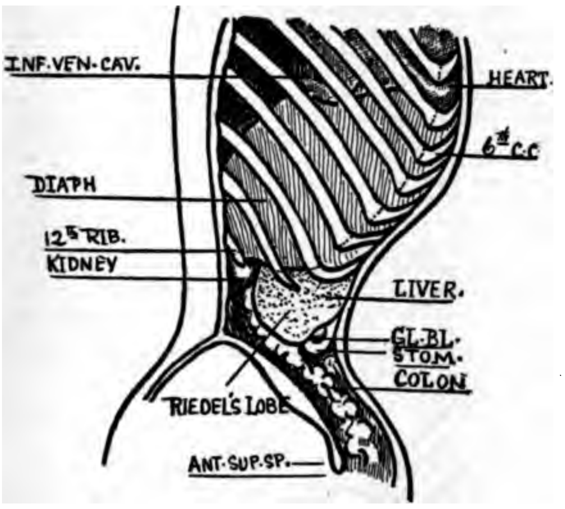

FIG. 5126.—Lateral View of the Same Subject. (Keith.)

It has been seen that the subjects of enteroptosis are mostly women. Those in whom the condition is marked are usually tall and thin, with no compactness of form, while the facial expression in many instances bespeaks a "neurasthenia basis," and, according to Keith and Williams, in cases of visceral ptosis, there is commonly a marked forward curvature of the cervical region of the spine—"ewe-neck."

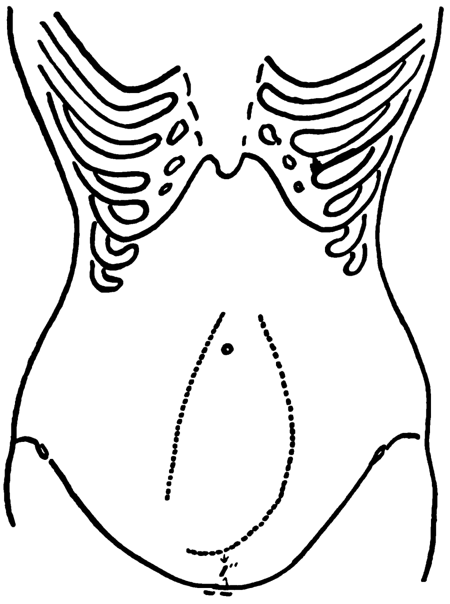

FIG. 5127.—Stomach Vertically Situated and Prolapsed. Located by Illumination.

The examination of the abdomen should be made in both the upright and dorsal positions. In the former attitude one finds, in typical cases, the lower part of the abdomen flaccid and prominent, overhanging the symphysis pubis—the "Hängebauch" of the Germans (Fig. 5126), contrasting strongly with the upper quadrants which are usually flat or hollowed out. Meinert holds that such a pendulous abdomen holds a dilated stomach and not a dislocated one. It is in the dorsal position, however, that one gets positive evidence of the postural anomalies of enteroptosis. The epigastrium is usually flat and somewhat scaphoid, with widespread pulsations, while the peri-umbilical region is prominent. Peristaltic waves may be seen crossing the abdomen from side to side; the recti abdominales are frequently widely separated, as may be shown either by palpation or by directing the patient to lift the head and

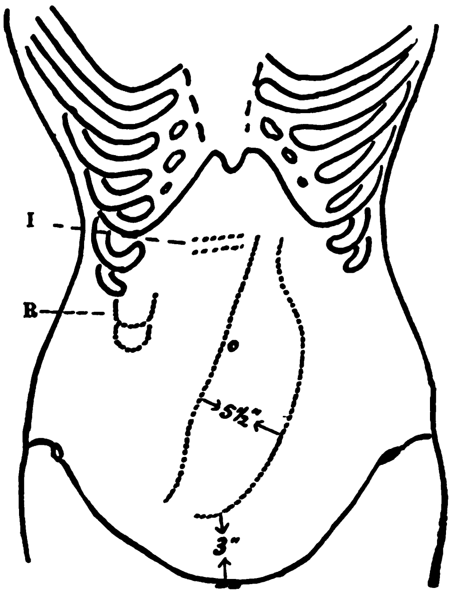

FIG. 5128.—Stomach Vertical or Nearly So. Located by Illumination. The "corde colique transverse" is well shown. Right kidney (*R*) is prolapsed.

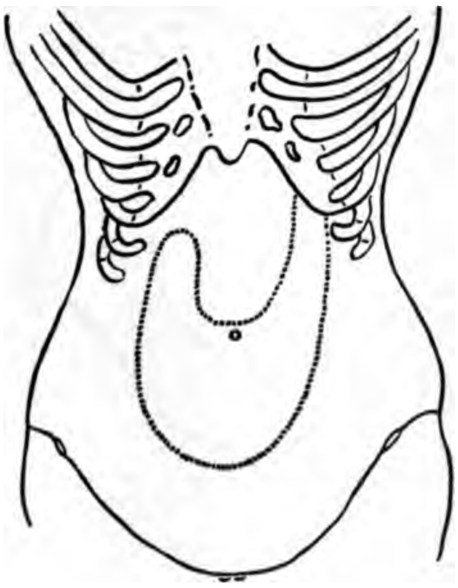

FIG. 5129.—Showing Tendency to V-shape of Stomach on Inflation.

shoulders unaided by the hands or elbows, when a prominent central ridge appears running from the ensiform cartilage downward. The usual methods for determining the positions of the different organs should be resorted to: palpation and percussion for the solid organs, while inflation and illumination, as well as auscultatory percussion, may determine the situation of the stomach, etc. Of these methods there seems but little doubt that inflation is the most accurate. It is important of course to distinguish between a displaced stomach and a dilated stomach. Indeed, when that organ is displaced it is usually dilated to some extent.

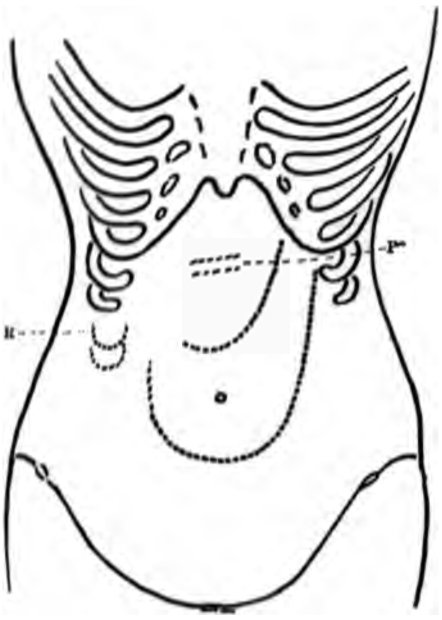

FIG. 5130. Showing Gastroptosis and Nephroptosis. *P*, The "corde colique transverse." (Pancreas is well shown.)

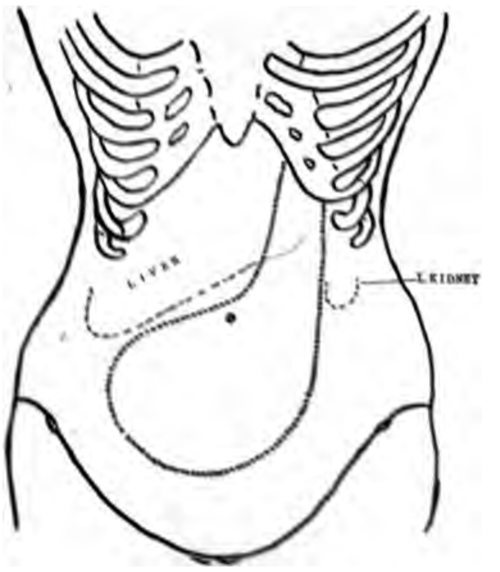

FIG. 5131. Showing Ptosis and Dilatation of Stomach. Ptosis of the liver and of the left kidney.

The organs usually found prolapsed, in cases of enteroptosis, are the stomach, the right kidney (movable or floating), and the colon (Fig. 5133). There is, however, increasing evidence to show that the liver is much more frequently dislocated than was at one time supposed. The left kidney and the spleen are implicated in this condition rarely as compared with the right kidney. The pancreas may be displaced also, chiefly at its head. Not infrequently the pelvic organs suffer the same displacement. The diaphragm and heart may participate in a general ptosis.

With reference to the determination of the position of the stomach, it is important to remember that normally the lesser curvature does not come into view when the organ is inflated, and that the whole of the organ lies above the umbilicus. Hence, when the lesser curvature is seen, and its normal relation to the greater curvature (four to four and one-half inches) is not greatly altered, gastroptosis is present, and in proportion as the lesser curvature approaches the umbilicus, or goes even below it, an increasing degree of gastric dislocation obtains. The stomach is sometimes seen in the oblique or almost vertical position (Figs. 5127 and 5128), and not infrequently the pyloric end is dilated, forming a three-quarter circle with the umbilicus as centre when outlined upon the abdomen. Again, the stomach may be somewhat V-shaped (Figs. 5129 and 5180).

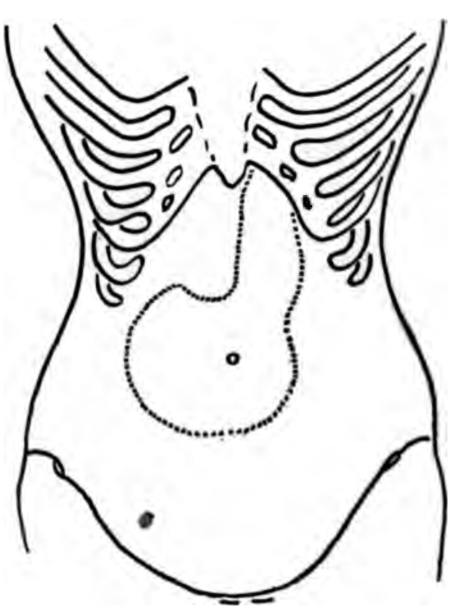

FIG. 5132.—From a Man with Kidney Freely Movable and Characteristic Symptoms.

What is the small band which is palpable running across the abdomen about two inches or so above the umbilicus? (Figs. 5128, *I* and 5130, *P*.) Glénard termed it "la corde colique transverse," and regarded it as the "colon transversum." There is good reason to doubt the correctness of this view. If the stomach is low the colon is generally lower, and in a case in which the band was most typically found by the writer, operation proved it to be the pancreas. In palpation of the abdomen Glénard laid special stress upon a test of considerable diagnostic value. The examiner, standing behind the patient, who is also in the erect position, places both hands flatly over the lower zone of the abdomen and applies firm and gentle pressure upward and backward. In the great majority of cases of enteroptosis this act affords considerable relief to the distressing dragging sensation felt in the epigastrium and abdomen. At the same time the result when "l'epreuve de sangle" is applied, is an index to the treatment. (I am greatly indebted to my house physician, Dr. J. R. Byers, for the accompanying illustrations.)

Stiller's Sign. (Costa fluctuans decima.)—Stiller regards enteroptosis as of a neurasthenic origin, and looks upon the presence of a floating tenth rib as indicative of the presence of a neurasthenic tendency. Observations upon this point reported by Meinert, Zweig, Arneill, and others, go to show that this sign in the diagnosis of enteroptosis, or neurasthenia, is scarcely so important as Stiller would have it.

With respect to the relation of enteroptosis, more especially gastroptosis, to chlorosis, it must be said that it is not that of cause and effect—no characteristic blood condition is found in cases of enteroptosis, and many cases of chlorosis occur in which there is no evidence of visceral displacements.

Jaundice, which has been seen in several cases, may
'esult from a variety of causes. "Gall stones are com-
nonly, if not always present, in cases of enteroptosis."
This statement, made by Dr. A. Keith, seems rather too
road, although it must be admitted "that the condition
f visceral ptosis favors their formation." However,
here can be no doubt that the altered relation of the bile
ucts and organs, especially the right kidney, the liver,
nd the duodenum, might in a variety of ways cause
bstruction to the outflow of bile and thus induce jaun-
ice.

PATHOLOGY.—It may be well before taking up the diag-
)sis of this condition to consider more particularly the
ithology of enteroptosis. The symptoms of enteropto-
s may be accounted for by various theories, which for
nvenience fall under three headings:

1. The mechanical theory of Glénard.
2. The neuro-mechanical theory of Meinert.
3. The neuro-intoxication theory of Schwerdt.

The first theory, though not a purely mechanical one,
es not ask for any antecedent nervous cause, but im-
es a weakness of the suspensory ligaments of the
nsverse colon, especially the colo-hepatic ligament.
e descent, Glénard claims, begins at the hepatic flexure
l the other events incident to the disease follow—
ero-stenosis, due to a kinking of the colon at the
nt of prolapse, the gastroptosis, the constipation,
o-intoxication, the neurotic manifestations, etc.

'nder the second theory Meinert attributes the symp-
is associated with dropping of the viscera to the con-
it stimulation and irritation of the sympathetic nerves,
result of pulling and stretching of these nerve fibres.
blood-forming organs and the general nervous sys-
participate in this abnormal irritation and stimula-
, and chlorosis, neuroses, and a variety of vaso-motor
irbances are thus induced.

hwerdt believes that the nervous system is primarily
ult; the fibre of the individual is toneless, the func-
of the abdominal muscles, both parietal and vis-
, are not normal; intra-abdominal pressure is les-
l, ptosis follows. There is a stasis in the blood and
h vessels, the bowel contents stagnate and decom-
excretions accumulate; absorption of poisonous
icts goes on, and intoxication is the result—dyspep-
eadache, anæmia, palpitation, neurasthenia, etc.

AGNOSIS.—In the great majority of cases one may
ct the condition from the complaints made by the
it—digestive disturbances, distress, not necessarily
in the stomach on getting up in the morning, or
being in the recumbent posture for some time,
ing under the right costal margin, a feeling as if
hing falls over to the left side when the patient
on that side, constipation, lack of energy, and other
thenic symptoms. The patient is generally slender
lean habit.

xamination of the abdomen, however, is necessary
ect or justify the suspicion derived from the com-
. The contour of the abdomen may further sug-
condition of splanchnoptosis and inflation of the
h by means of tartaric acid and bicarbonate of
r air cautiously pumped in, readily and accurately
to locate that organ. The solid organs may be
d, and it is recommended to examine the liver
he patient is in the upright position. Displace-
of this organ are doubtless much more frequent than might be supposed, judging from the results of examination in the dorsal position. The right lobe of the liver in some cases projects in a tongue-like process below the costal margin. It has been described as Riedel's lobe, and may occasionally be somewhat misleading. The test known as "l'epreuve de sangle," already described, should be applied in all suspected cases. It is scarcely possible, after a careful examination, to mistake enteroptosis for any other condition. Doubtless many cases of gastric neurasthenia and of nervous dyspepsia would be cleared up by a careful search for visceral ptosis.

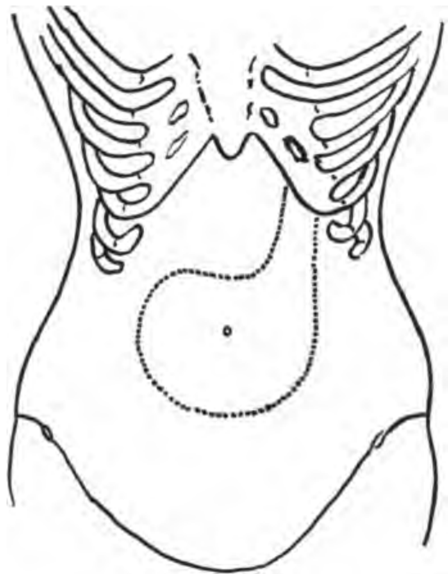

FIG. 5133.—From a Case of Pulmonary Tuberculosis. Gastroptosis with dilatation of the pyloric end, showing as a three-quarter circle; the umbilicus as centre.

Among others at least two instances of mistaken diagnosis coming under the writer's notice may be recorded. In one, a diagnosis of malignant disease of the stomach led to a laparotomy revealing the pancreas as the palpable misleading mass, while in the other, recurrent jaundice was thought to be due to gall stones or a "sluggish liver," and the horseback riding, rowing, walking, canoeing, recommended for its relief, aggravated all the symptoms. On the other hand, there is danger of attempting to explain too many symptoms by visceral ptosis.

PROGNOSIS.—Many patients recover entirely, losing all symptoms and signs of the disease. The majority may recover from the evil train of symptoms, the ptosis existing in part at least. It may be fatal as the result of the exhaustion and intoxication in extreme cases.

TREATMENT.—The indications for the treatment of enteroptosis as originally recommended by Glénard can scarcely be improved upon. They are as follows:

1. The intestines must be elevated and kept in their new position.
2. The abdominal pressure must be increased.
3. The bowels must be regulated.
4. The secretions of the intestinal glands must be increased.
5. The digestion and nutrition must be regulated and stimulated.
6. The whole organism must be strengthened.

If a cause can be fixed upon as inducing or aggravating the displacement, let it be removed. Those measures will best meet all these requirements which increase the strength and raise the tone of the whole musculature. It seems in most cases to be a question of nutrition, rest, good food, mild yet efficient purgatives, or better still enemata, occasionally gastric lavage, with drugs directed against fermentative processes in the early stages of the treatment, as indicated. It is of the highest importance to increase the strength of the abdominal muscles by regulated exercise. Belts, or abdominal supporters, so highly recommended and in such variety, are of doubtful utility. Only those belts which increase the intra-abdominal pressure should be used. They encircle the abdomen and exercise the same degree of pressure over the whole abdominal surface. It is not only futile, but often harmful, to attempt to hold a kidney or a stomach in place by any special device externally applied.

With respect to surgical treatment of this condition, it must be said that it should be undertaken only after other methods have failed, and then only with the greatest care, especially in those cases in which the neurasthenic element is strongly manifest, for such patients are often worse rather than better after surgical interference. Duret first operated in 1894, lifting the stomach and fixing the serosa of the lesser curvature of the stomach to the parietal peritoneum and muscle of the anterior wall of the abdomen. Byron D. Davis (1897), Beyea (1898), Hartmann (1899), Treves, Bier, and Webster, have operated with varied success on similar cases. Beyea and Stengel shortened the gastric hepatic omentum and gastrophrenic ligament by plicating with multiple sutures, thus bringing the stomach up to its normal position. Webster, selecting those cases in which there was separation of the recti muscles, sought to increase intra-abdominal pressure by resecting the fascia of these muscles and then suturing the muscles together.

ERYTHROL TETRANITRATE.

[illegible]

tation, and several hours for the effect to wear off. The dose is gr. ¼–i. (0.015–0.06 gm.), most conveniently administered in tablet triturates. Bradbury recommends ʒ i. (4 c.c.) of a 1 in 60 alcoholic solution repeated every four to six hours.

W. A. Bastedo.

ERYTHROMELALGIA.—This affection was originally described by Weir Mitchell in 1872 as follows: "A chronic disease, in which a part or parts—usually one or more extremities—suffer from pain, flushing, and local fever, made far worse if the part hangs down," and writers since then have not been able to agree upon a definition more satisfactory than this descriptive one. Up to the present time about one hundred cases have been reported and discussed by neurologists and pathologists, the questions of its pathogenesis, and of whether the affection is properly a distinct disease or entitled only to be called a group of symptoms, having excited much interest. To these topics we shall return in their proper place.

The subjects of erythromelalgia are usually middle-aged people, sometimes young adults, but seldom children. Many more males are attacked than females, and the predisposing causes are such as men are more liable to than women, viz.: occasionally traumatism, as from a stone falling upon the foot, exposure to wet and cold, especially when repeated, long standing at fatiguing work, sometimes exceptionally exposure to heat, as in working at a furnace. Also malaria, syphilis, anæmia, alcoholism, hysteria, and dyspeptic states are all believed to stand in a causative relation to it. It is also found associated with various other general diseases, and particularly those of the nervous system. Reynolds mentions one case as coming on suddenly soon after confinement.

Symptoms.—The most distinctive and fundamental symptoms are those originally emphasized by Weir Mitchell. He also in his most recent paper on the subject reminds us that the pure type of symptoms should be looked for in the youngest class of patients, for in those who are more advanced in life diseased conditions of the arterial or nervous system may exist independently of erythromelalgia and [illegible]. The local symptoms [illegible] the peripheral parts of the extremities. The [illegible] characteristic symptoms [illegible] suggestive of inflammation [illegible] distinguished from [illegible]

[illegible]

ıe relief of which incisions have been made, which,
)wever, revealed nothing.

The seizures thus characterized were called by Mitchell
vascular storms." They may last for several hours or
ay extend to days or weeks, the local feature sometimes
tending to parts not originally involved. The seats of
tack are sometimes symmetrical, sometimes not. But
addition to the symptoms already mentioned others
ɔw themselves, which have been considered not char-
eristic of erythromelalgia, and which are not con-
nt, but still may be of importance as bearing upon its
thogenesis. Thus Elsner and Barlow speak of hyper-
osis accompanying the paroxysm, of "innumerable
plets of perspiration standing upon the skin at the
e of the most acute pain." There may be a condition
cribed as local asphyxia, which may merge into cya-
is. The pulse is often quickened, which, taken in
nection with the changes in the circulation, may be
index of more than local vaso-motor disturbances.
ions of sensibility are frequently present, hyperæs-
ia and paræsthesia most commonly, but are by no
ns constant enough to be regarded as characteristic
ıe disease; nor is the motor function often interfered
ı, the lesions when occasionally encountered in the
advanced cases being present as weakness and pare-

There is sometimes muscular atrophy. Reflex irri-
ity is infrequent. The *trophic* lesions associated with
ɔcal manifestations are frequent and multiform. The
may be either thickened or show changes analogous
e "diffuse idiopathic atrophy of the skin," of derma-
ists, as in a case reported by Schütz. There are
times pigmentation and œdema, and lumpy alter-
s of the joints and nails; also rhagades and ulcers
develop. It is also quite common to find nodules or
les on the reddened and painful areas (Kahane).

ɔther symptom which sometimes presents itself is
ene, considered by some to be a feature of indu-
e cases of erythromelalgia, its occurrence depend-
pon the greater or less severity of the disease
), and by others as indicating its alliance with
ud's disease.

itchell in his earlier publications refrained from
ve expression of opinion as to the origin of the
ut later (1878) regarded it as "a *vaso-motor neu-*
h might occur either independently or in asso-
th spinal or cerebral disease, where some dis-
ons of definite regions might ultimately be
." Subsequently he expressed the view that
melalgia a neuritis of the finest nerve twigs
resent. Lewin and Benda, writing in 1894,
most thoroughly discussed all the cases that had been reported up to that time. They classify these cases under three headings: 1st. Erythromelalgia in organic diseases of the central nervous system. 2d. In functional diseases of the central nervous system (neuroses). 3d. As a peripheral affection (neuritis and neuralgia), the latter group embracing half of all the cases. The vasomotor symptoms are always secondary to the neuralgic pains. In answer to the question whether it is an independent disease, their conclusion is that it is not a disease *sui generis*, but may be associated with various peripheral and central diseases of the nervous system.

In 1895 Eulenburg wrote that 'he had reasons for "thinking that the starting point of the disease may be found in certain sections of the gray axis of the cord, especially in the posterior and lateral gray substance, and the associated fasciculi," an opinion which has had great weight.

Auerbach in 1897 published a report of the first complete autopsy made on a case of this disease. There was a normal condition of the peripheral nerves and spinal ganglion cells, marked degeneration of numerous radical fasciculi (Wurzelbündel) in the cauda equina, on one side more than the other, belonging to the first or second sacral nerve and the last lumbar nerve. Pronounced ascending degeneration in the cord."

In 1899 Weir Mitchell and Spiller report that in examining an amputated toe from a patient with erythromelalgia there were found a high degree of degeneration of the nerves, which were almost completely converted into connective tissue, also extreme changes in the vessels, thickening of the media, hypertrophy of the intima, and in places complete closure of the lumen of the artery; and on this finding peripheral neuritis was assumed as the basis of the disease. In this article the opinion is still held that certain cases may be due to some form of spinal disease, but the idea of a nerve-end neuritis is urged. These examinations and others give greater definiteness to the discussion of the pathological relations of the central and peripheral organs in the development of the disease. In Dehio's case 4 cm. of the ulnar nerve and an equal length of the ulnar artery were removed just above the wrist for erythromelalgia involving the hand. The little finger improved, but the rest of the hand remained unchanged. Examined under the microscope the piece of the nerve was found normal, but the artery showed marked arteritis of the middle and inner coats and some diminution of the lumen. Barlow indicates three directions in which inquiry as to the pathology should extend: 1st, to the peripheral nerves; 2d, to the brain and cord, especially in regard to the vaso-motor centres; and 3d, to the blood-vessels. He declares that the disease has been generally regarded as a vaso-motor neurosis or paralysis, and concludes that "in the absence of obvious nerve disease to explain the arterio-sclerosis we are led back to the hypothesis that the chief fault lies with the vaso-motor centres and their abnormal efferent vaso-motor impulses leading to dilatation of the vessels and consecutive disease induced thereby. Some peripheral strain or irritation may have been transmitted to the vaso-motor centre as the original cause of the disturbance." He further expresses the belief that probably the change in the vaso-motors starts centrally, especially in the generalized cases of the disease, although it is more reasonable to suppose that in uncomplicated cases the primary change starts at the periphery. The question whether erythromelalgia is an idiopathic affection or should be considered merely a group of symptoms appearing in association with various primary diseases has brought out a diversity of opinion. Collier in 1898 says it is not now regarded so much as an idiopathic disease as a group of symptoms occurring in other affections, and Kahane, writing in 1900, quotes Lewin and Benda, Eulenburg and Levi as holding the same view, and says the conclusion reached in all the larger comprehensive statements about erythromelalgia is that it is no individual disease, but a symptom-complex accompanying various other diseases of the nervous system.

Kahane himself, however, finally gives as his own opinion that it should be ranked among the acropathies, which he defines as those affections which are localized in the peripheral parts of the limbs and as the ultimate basis of which are assumed lesions of a vaso-motor nature. There is great difficulty in determining whether the nerves or the vessels form the starting point, whether we have to do with an irritation of the vaso-dilators or a paralysis of the vaso-constrictors. He says, in conclusion of a long and careful consideration of the question, that there are two points that one can be sure of: 1st, that erythromelalgia belongs clinically to the group of acropathies; 2d, that it is to be referred to a disturbance in the relation between the systems of the nerves and blood-vessels quite without regard to the question whether it is of functional or anatomical, central or peripheral nature. In his conception it is a phase of disease that occurs in one series of cases independently and in another as an attendant phenomenon of other diseases.

Sachs had found the blood-vessels diseased in most cases, but the nerves not in many; the changes in the latter he believed to be secondary. He says erythromelalgia occurs as an independent group of symptoms, even if not an individual disease. In uncomplicated cases it is probably to be referred to disease of the peripheral arteries. The obliterating arteritis may be indirectly connected with central disease, but may be wholly independent of such influences. In 1901, Elsner, on examination of the arteries in cases that he saw, found them the seat of occasional slight thickening of the intima, but the nerves normal. He calls attention to several cases in which gangrene of the extremities occurred. He believes that erythromelalgia cannot at present be defined as a disease *per se*. Cassirer, on the contrary, is constrained to place himself among those who believe the disease to have a certain idiopathic character, while recognizing like others one class of cases of a peripheral and a second of a central origin. Allchin and Saville regard the disease as of vaso-motor origin, probably allied to Raynaud's disease, the former speaking of it as an expression of vaso-motor ataxia. Shaw in 1903 analyzes nine cases and reports the results of the examination of amputated toes in three cases, stating that "vascular change was present in all, mostly an increase in the intima of the arteries and occasionally thrombosis and changes in the inner coat of the veins. The nerves were investigated even to their terminations, and no degeneration was found, nor was there any suggestion of increase of fibrous tissue in the trunk of the nerves." (Compare Mitchell.) He says: "In no case has recent degeneration of nerve fibres been demonstrated, and in not one of the nine cases analyzed was anæsthesia ever present." He concludes that erythromelalgia when occurring independently of central nervous change is associated with but one morbid picture, that of local vascular change. Taubert finds erythromelalgia traceable to disease in the lateral and posterior columns of the cervical cord (see Eulenburg and others). Reynolds calls the disease a vaso-motor neurosis, and argues in favor of the theory of primary vaso-motor dilatation of the arteries followed in the way of compensation for this vaso-motor paralysis by thickening of the coats of the arteries so as to narrow the lumen and stream of blood (quoting Delafield, Thoma, and Barlow in support of his views). Starr, sketching the phenomena of the "vascular storm," says: "The dilatation of the arteries in the extremities results in an extreme condition of redness and sensation of heat and pain. After hours of this the extremities may suddenly become cold, pale, or blue and shrivelled up, presenting the appearance of the hands after long soaking in hot water; and this alternation of distention and contraction of the blood-vessels constitutes the symptomatology of the disease. It appears to be a pure vaso-motor neurosis, but it is rarely if ever attended by any trophic disturbances of the skin or nails, such as occur in neuritis, and no pathological observations are at hand to establish the hypothesis that there is a true neuritis of the vaso-motor nerves."

If, thereore, we should venture upon a rough summing up of the principal pathological features of erythromelalgia as indicated in the preceding brief synopsis of recent authorities we should say that opinion was settling upon the following beliefs: (1) The disease is considered a vaso-motor neurosis (angioneurosis, Oppenheim); (2) the attribution of the group of symptoms to disease of the posterior and lateral spinal gray matter, when it would be called secondary, and to as yet undetermined causes of peripheral origin, where some would call it clinically idiopathic or *sui generis*; (3) its association with the acropathies and sometimes with Raynaud's disease; (4) there is much more evidence connecting the disease locally with alterations of the blood-vessels than of the nerves, but good authorities deny that we are yet in position to pass finally upon its pathology.

The TREATMENT of erythromelalgia can hardly be said to aim with hopefulness at more than the alleviation of some of its most distressing symptoms, proof of which is found in the long list of the various means employed. Weir Mitchell's recommendation of rest, cold, and elevation of the limb affected has been found of value, based as it is upon well-known observations of patients that the opposites of these increase their sufferings. Other measures to be noted are hydrotherapy, electricity (Eulenburg and Schütz found benefit from the use of the constant current), massage (although Barlow says it is of doubtful value and unbearable during the paroxysms). Of course antisyphilitic remedies are indicated in cases in which that disease is believed to underlie or complicate erythromelalgia, and among drugs which are more or less approved are arsenic, antipyrin, the bromide of potassium, morphine (Morgan reporting a case of recovery after hypodermic injections of morphine and atropine twice a day for three weeks), the salicylates, atropine, and ergot internally as well as ichthyol externally. It should also be remembered that spontaneous recovery has taken place in some cases. Further than this, the several cases referred to above are evidence that surgical measures, such as the stretching of nerves, their resection, and the amputation of toes and fingers, have brought relief in certain instances. It should be noted, however, that gangrene followed operative procedures upon nerve and vein in one case of Weir Mitchell's and upon amputation of a toe in another.

The references given below are mainly to the chief articles of the last three years, the reader being referred to the essays of Lewin and Benda and of Kahane for full bibliographies.

EUCAINE is a name applied to two different but closely llied local anæsthetics distinguished as *Alpha-eucaine* r *Eucaine* "*A*" and *Beta-eucaine* or *Eucaine* "*B.*"

The anæsthetic effect of cocaine, which is methyl-benoyl-ecgonine, $C_{17}H_{21}NO_4$, was found to depend on the resence of both the methyl and the benzoyl groups and ot on the ecgonine radical. So with the desire of obining the anæsthetic effect of cocaine without its toxity, other methyl-benzoyl compounds were designed. f these Eucaine "A" was submitted to the profession, d was for a time extensively employed; but its very ritating effects have so militated against its desirability at it has been largely replaced by its congener, Eucaine 3," a compound of less toxicity and less irritating propties.

Alpha-eucaine, $CH_3.N.C_2.(CH_3)_2.(CH_2)_2.(CH_2)_2.CC_6$-$_5$COO.COOCH$_3$, is methyl-benzoyl-tetra-methyl-hyoxy-piperidine-carbonic-acid-methyl-ester, a derivative tri-acetone-amine. Its hydrochloride occurs as a bitter ite crystalline powder soluble in 10 parts of cold ter, 7 of boiling water, less than 2 of alcohol, and 18 glycerin, and is very slightly soluble in ether and the d oils.

Beta-eucaine, $H.N.C_2.HCH_3.(CH_3)_2.(CH_2)_2.C.C_6H_5$-O.H, benzoyl-vinyl-diacetone-alkamine, is also a bitter ite crystalline powder, and its hydrochloride dissolves 23 parts of water, 12 of boiling water, 30 of alcohol, 35 of glycerin. It is insoluble in ether and almost luble in the fixed oils.

oth eucaines have the nature of alkaloids, and their rochlorides have been the salts in common use; but acetate of beta-eucaine is now recommended as it is lily soluble in water. The solutions of eucaine salts not decomposed by boiling, so may be sterilized.

he pharmacological action of the eucaines has been ied by Cushny, Vinci, Ver Eecke, and others. The are not absorbed by the unbroken skin, but, applied ucous membranes or injected into the tissues, they lyze the sensory nerves and their terminal endings at ite of application and are powerful local anæsthetics. are said to produce local congestion in mucous branes.

large dose they weaken the heart by direct depres- of the cardiac muscle and its contained ganglia, and dition lower blood pressure by dilatation of the arte-. The respiratory centre is at first stimulated, later yzed, so that death takes place from asphyxia (par- of respiration). The cerebral centres are stimu- with the production of tonic and clonic convul-; later they are paralyzed. There is no dilatation of upil or disturbance of the accommodation of the ut the conjunctiva is congested. The superficial lium of the cornea is not affected. The kidney cells imulated and the quantity of urine is increased, increased elimination of nitrogen, phosphorus, and les. The drug is not found in the urine, and ap-ly undergoes decomposition in the body.

produce general poisoning in rabbits and guinea-t requires 0.15–0.2 gm. of eucaine "A" per kilo, 4–0.5 gm. of eucaine "B." Cocaine is four times sonous as eucaine "B," and only slightly more han eucaine "A."

uses of beta-eucaine as a local anæsthetic are prac- those of cocaine, so we need not here enumerate its eutic applications. The consensus of opinion surgeons (Bier, Bainbridge, Moyer) would seem to that it is weaker as an anæsthetic than cocaine, r employed subcutaneously or in spinal analgesia. found that the amount required for a small n averaged ʒ i.–iss. (4–6 c.c.) of a four-per-cent. , but G. W. Crile performed a painless duodenos-ith 8 c.c. (ʒ ij.) of a two-per-cent. solution.

y all writers agree that eucaine tends to increase emia of the conjunctiva or nasal mucous membrane, and Dawbarn and others prefer it for the removal of tonsils, adenoids, and other hypertrophied tissues, as it does not cause a shrinkage like cocaine. Poole prefers cocaine in iritis, as eucaine increases, or at least does not decrease, the anterior congestion.

In our experience eucaine applied to mucous membranes is slower in its action and much weaker than cocaine; used subcutaneously it is somewhat weaker. We had several cases of local gangrene following its hypodermic use in abdominal and pleural tapping, though in each of these instances the injection had been preceded by the ethyl-chloride spray. Cocaine under similar conditions never produced a slough. Da Costa noted a slow, persistent sloughing, especially in fatty tissue, bursæ, or tendon sheaths. He also noticed inflammation following its use in the bladder. Shastid reports the occurrence of amblyopia, rapid pulse, and delirium following the application of a five-per-cent. solution to the inferior turbinate.

Beta-eucaine is, then, a drug of anæsthetic action resembling that of cocaine, but somewhat weaker. It produces hyperæmia rather than the ischæmia of cocaine, and has no effect on the pupil, accommodation, or the corneal epithelium. In the ordinary dosage it is nontoxic, and is reported to be well borne where there is an idiosyncrasy against cocaine. Lilienthal has frequently used four to ten grains without unpleasant consequences. No eucaine habit is known. The drug keeps indefinitely and can be sterilized by boiling.

Solutions of one- to four-per-cent. strength in normal salt are commonly employed, but stronger solutions, obtained by heating the liquid and using warm, are sometimes preferred. Von Mikulicz uses the following: ℞ Cocainæ hydrochloridi, 0.5 gm. (gr. viiss.); beta-eucainæ hydrochloridi, 0.5 gm. (gr. viiss.); sodii chloridi, 2 gm. (gr. xxx.); aquæ, q.s. ad 1,000 c.c. (℥ xxxii.).

W. A. Bastedo.

EXOPHTHALMIC GOITRE.—(Synonyms: Graves' disease; Basedow's disease.) These names have been indifferently used during the last sixty or more years to express a fairly well-defined disease in which more or less enlargement of the thyroid, protrusion of the eyes, and certain nervous disturbances (including tachycardia) form the prominent symptoms. The Irish physician, Graves, who described the coexistence of palpitation of the heart with enlargement of the thyroid as an affection more or less related to hysteria, was antedated in his observations by Parry, who mentioned the same combination together with exophthalmos in 1825. Some years later Basedow also observed the existence of exophthalmos in similar cases, and gave the description which has connected his name with the disease. Charcot, too, in 1844 and 1845 described such cases at the Salpêtrière. Since their time an enormous literature has appeared in which, while the objective descriptions remain very constant, the most divergent theories have been advanced to account for the symptoms. These we may detail in discussing the etiology of the disease.

Exophthalmic goitre is an affection which occurs most frequently in women, although cases are by no means rare in which the same phenomena are seen in men. No very precise age limits can be set, but the majority of the cases appear to begin after the age of puberty, and to increase in number as the climacterium is approached, the onset being most frequent, according to Osler, between the ages of twenty and thirty. No particular station in life seems to predispose to the disease, but it is usually observed that the individuals belong to neuropathic families in which cases of epilepsy, hysteria, chorea, or even some form of insanity have occurred. Combinations of epilepsy and exophthalmic goitre in the same person have been described,[1] in which cases the epileptic seizures usually give place to the symptoms of the other disease. Exophthalmic goitre is a very widespread disease, not at all localized in certain areas, as is the case with other forms of goitre and with endemic myxœdema or cretinism. Indeed, although cases in which exophthalmic symptoms supervene after the long existence of the ordinary type of goitre are not unknown, the disease seems to be no more frequent in those regions where goitre is endemic than elsewhere, and the coincidence of the two conditions must be considered accidental. Instances of the coexistence of exophthalmic goitre with myxœdema have also been observed,[2] which, although probably accidental and not indicating any close relationship between the two conditions, have a significance which will appear later.

SYMPTOMS.—The onset is sometimes very slow and gradual, in other cases it is extremely sudden, and the symptoms reach their maximum of intensity in a very short time. Usually, but not always, such an onset is ascribed to sudden violent emotional disturbances, such as a fright or great sorrow, etc., after which the patient feels demoralized and incapable of effort, and the palpitation of the heart and tremors begin. Prominence of the eyeballs may be the first thing observed, and is noticed by the friends before the patient herself appreciates it.

Of all the symptoms perhaps the most constant are those referable to the heart and circulatory system in general, and these may be considered under several heads. First of all and most noticeable is the violence of the heart's action—a pounding heart beat that may sometimes be violent enough to keep the patient awake can be felt over a wide area. Loud systolic bruits can often be heard over the apex and base of the heart and along the vessels. The pulsation of the arteries is extraordinarily violent in many cases and is readily visible in the extremities. There is usually a widespread dilatation of the capillaries also, and sometimes a venous pulsation can be made out. The dilatation and violent pulsation of the vessels are especially noticeable over the enlarged thyroid and in the eye grounds.

Then next in prominence is the tachycardia, which may reach the highest degree. Usually this develops gradually and the pulse rate increases from normal up to 130 to 150 or more in the minute. In a case recently observed in the Johns Hopkins Hospital, a rate of 200 per minute was maintained for days. The tension in such cases usually remains high, and the volume full. F. Müller[3] gives a sphygmographic tracing in a case whose pulse rate at the time was 176, in which this is illustrated, there being a sharp initial elevation with frequent bigeminal pulsation. Recent researches seem to show (Donath,[4] Spiethoff[5]) that the blood pressure is in some cases increased, in some diminished, but by no means always increased.

Variations in the pulse rate are very marked, and excitement or exertion has a much greater influence than in a normal individual. In some instances it is impossible to escape from the idea that exhaustion of the heart muscle must play a part in the final dissolution of the patient.

Referable to the central nervous system more directly we find a variety of symptoms, of which perhaps the most prominent is the tremor. This is involuntary and fine for the most part, leading to a fine trembling of the hands, muscles of the face, and indeed of any and all of the muscles indifferently. It is most noticeable to the patient in the attempt to perform fine co-ordinated movements. Writing becomes difficult or impossible, and the characters show a tremulous irregularity. Fibrillary twitchings of the tongue are usually present, and may be so extensive as to produce a wave-like undulation over the surface of that organ. Definite spasms and twitchings of various muscles may occur too, even producing in some cases the condition of tetany, such as has been described in thyroidectomized animals. Epileptiform seizures are not unknown, and may suggest an extreme manifestation of the tetanic condition. The explanation of these phenomena will be further discussed in treating of the etiology.

The other symptoms referable to the nervous system are chiefly psychical. Early in the disease the patients feel themselves to be irritable and excitable. The friends observe a change of disposition, very different from that observed in the development of myxœdema. Instead of becoming sluggish and apathetic, with all the mental faculties dulled, these patients are keenly susceptible to every outward stimulus, and the mental reaction is a relatively intense one. In some respects this receptive and reactive state may resemble in a mild way that seen in the maniacal stage of the maniacal-depressive insanity. A feeling of anxiety often dominates the mental state and the excited patient becomes a prey to groundless fears. Insomnia may be persistent, much to the exhaustion of the patient. In other cases fantastic dreams occur with great frequency, and may pass over into the waking state, so that the patient has but to shut her eyes to see all sorts of forms move about her, or even in broad daylight the hallucinations may occur. Delirium and the wildest maniacal excitement, or stupor and even unconsciousness may come on late in the disease.

The exophthalmos is not an invariable feature, although it is very frequently present (Fig. 5184, *A* and *B*); it may be unilateral, but is usually bilateral. In its onset it becomes, as a rule, gradually more and more noticeable, but sometimes, as it is alleged, after a sudden emotional shock it may appear and reach a high grade within a very short time. The actual extent of the protrusion of the eyeball it is difficult to measure, although methods have recently been devised which will render such measurements more exact. It is most noticeable in the widening of the aperture of the lids which it produces, and by the staring expression which it gives to the face; but it must not be forgotten that the individual variations in normal people in this respect are very great. In extreme cases, however, such as one of Basedow's, the eye may be actually dislocated from the orbit. Many consequences of this protrusion have been noted in the literature, and as signs of the exophthalmos they bear the name of their observers. Graefe, for example, noticed that in lowering the eyes the upper lid did not follow and keep the sclera covered as in the normal eye—the so-called Graefe's sign. Stelwag's sign consists in the widening of the palpebral aperture; Möbius' sign, in the lack of normal convergence of the eyes.

Pupillary changes are rarely if ever seen, and no definite retinal alterations have been found, nor is there any disturbance of sight from the exophthalmos proper. Winking is much less frequently carried out, however, than in the normal eye, and in cases in which the eye projects far from its socket the eyelids never quite cover the eyeball. The consequence may be that the proper moistening of the surface is interfered with, and a band-like area across each eye, passing over the cornea, becomes dried and opaque. Ulceration and infection of this dried area, which becomes wider with the increased protrusion, leads to complete opacity of the cornea and loss of vision in that eye. The infection may even go on to involve the whole eye and result in its entire destruction.

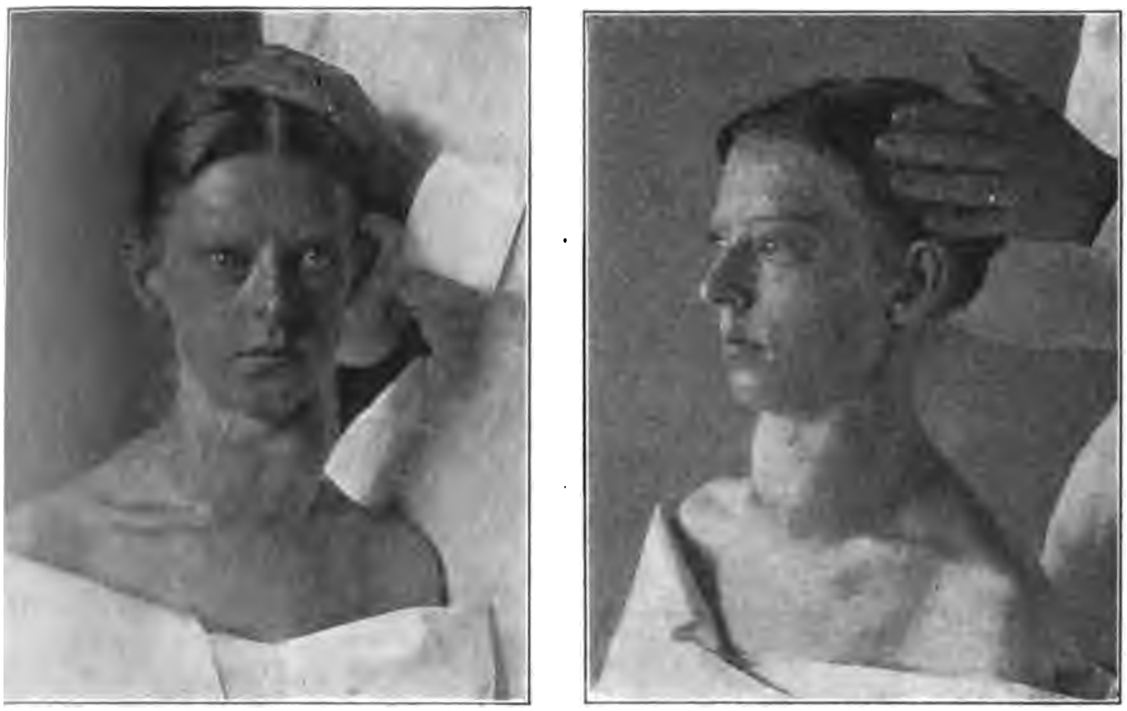
The absence of pupillary disturbances is particularly significant in connection with one of the theories as to the etiology of the disease, as will appear later.

No special disturbance of the urinary secretion seems to occur with this disease, although glycosuria has been observed in some cases and polyuria in others.

Digestive disorder and disturbances of the general metabolism, however, are almost constant, and have an extremely important bearing upon the prognosis.

Loss of appetite is very common, and the patients waste away perhaps as a result of this. On the other hand, a ravenous, insatiable appetite is sometimes observed, but strangely enough with the same progressive emaciation. F. Müller[6] describes most graphically this curious phenomenon. "The food prepared for this patient, quite enough for the nourishment of a robust person, was not enough for her, and she gathered up every scrap of food that was left by the other patients in the ward. One found her almost always eating, and it was curious to see her, as with wide open, eager eyes she stared into her plate and ceaselessly chewed and swallowed."

There are, however, variations in this emaciation, such



A. *B.*

FIG. 5134.—Case of Exophthalmic Goitre showing Exophthalmos and Goitre. *A*, Front view; *B*, side view.

hat while at times the patient loses rapidly in weight, here come periods during which she recovers almost all hat was lost, and Huchard speaks accordingly of "crises l'amaigrissement." The loss of weight may be enormous d astoundingly rapid. One of Müller's patients lost y pounds in nine months, reaching then a weight of y-four pounds. Curiously enough the emaciation y not be general but limited to one portion of the ly, either to one side or to the upper part, while the ver extremities remain unaltered. von Schrotter[7] de- ibes such a case in which the very fat legs contrasted rply with the wasted chest and shoulders.

)iarrhœa, of a most persistent character, is often ob- ved, and may aid greatly in producing the emaciation. seems possible that it may be due to an increased ivity of peristalsis dependent upon some such nervous uence as produces the general tremor. Incidentally, , it may be remarked that it seems possible that in se cases of persistent diarrhœa which are associated h tetany there may be an underlying cause for both, ilar to that at work in the production of the disease ler discussion.

ymptoms from the genital apparatus are very incon- it and difficult to explain. There is sometimes a ces- on of the menses, and there have been instances in ich pregnancy has had a favorable influence upon the rse of the disease.

hanges in the skin are frequent and of many sorts. y characteristic is the profuse and continued sweat- which is no doubt due to the central irritation of the etory nerves. It is frequently such as to bathe the ent constantly and to keep the skin in a sodden lition, from which results the increased electrical luctivity noted by Charcot and others. Annoying ations of heat, accompanied by flushing of the skin, uently occur, while the general temperature is nor- . Other changes, difficult to explain, also appear, i for example as the extensive pigmentation of the , which may be almost like that observed in Addison's disease. An instance of this is the above-mentioned case of von Schrotter. So, too, urticaria, erythema, localized œdema, scleroderma, loss of hair, swelling of joints, atrophy and hypertrophy of breasts, etc., occur, and are usually explained as dependent upon disturbances of the trophic nerves.

Dyspnœa and labored breathing may come on, especially after exertion, and occasionally there is a dry cough which is very wearing, but which seems not to depend upon any actual pulmonary lesion.

Finally the thyroid shows fairly constant changes, which are recognizable clinically (Fig. 5134, *A* and *B*). The enlargement is usually diffuse and bilateral, but may not be extreme. Frequently it is so slight as to be hardly noticeable.

In all cases, however, the thyroid is somewhat increased in consistence and may sometimes become very hard. The vessels which course over it are generally widely dilated and pulsate violently, and to this great vascularity and hyperæmia is due in large part the enlargement of the gland.

PATHOLOGY.—Numerous autopsies have been performed on these cases, and the most painstaking examination of the viscera made without as yet any constant lesion having been discovered which can be considered explanatory of all these symptoms. Especial attention has been directed to the nervous system and to the thyroid, and the description of the changes in these can therefore be made more minute.

In the central nervous system no definite constant changes have been discerned in the cerebral cortex nor in the lower portion of the brain or cord. Only Mendel[8] and his students have found atrophy of the corpus restiforme on one side with a similar atrophy of the solitary bundle on the other side, and this he brings into causal connection with the disease. It is, however, far from constant, and it is hard to explain a general condition by a one-sided lesion.

The sympathetic ganglia in the neck have also been examined with great care, but Ehrich,[9] who from his cases was able to find degenerative changes, thinks them entirely secondary. Others find no alterations whatever in these ganglia and nerves.

Müller found degenerative changes in the trunk of the vagus nerve, but decided that these were secondary.

The alterations in the heart are by no means constant nor characteristic. Dilatation is sometimes found at autopsy, hypertrophy occasionally, while degenerative changes are frequent.

It is in the thyroid that the most characteristic and constant changes are met with. The gland is usually but not always enlarged, and its consistence much increased. No adequate idea of the vascularity is gained from the inspection of the specimen after death, but at operation it is found to be extraordinarily rich in widely distended vessels, which pulsate violently, and which from the friability of their walls (Kocher,[10] Ehrich [11]) render the operation for the extirpation of the gland a difficult one. The surface is often somewhat nodular and the capsule thickened. Section of the gland shows that it has not the translucency and brownish-red color of the normal gland, nor its gelatinous elastic consistence. Instead it is hard and resistant, and of an opaque pinkish-gray color, the cut surface having a rather lobular, roughened appearance. (Figs. 5135 and 5136.)

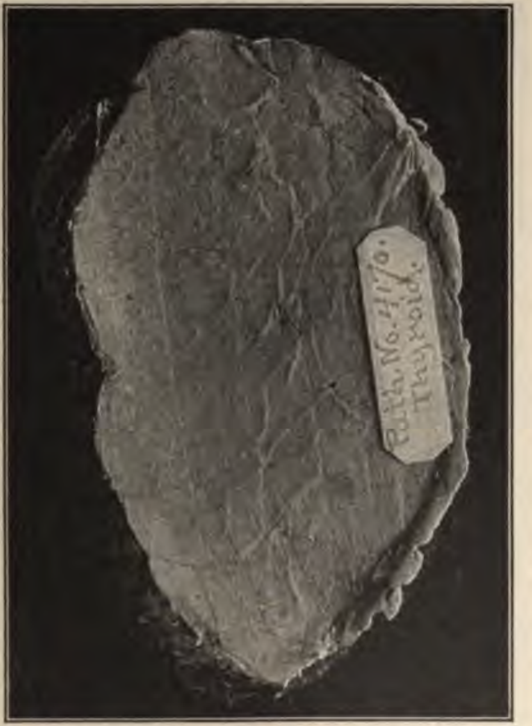


FIG. 5135.—Exophthalmic Goitre. Thyroid lobe in section from case illustrated in Fig. 5134.

Microscopically there is usually made out a great increase in the connective tissue throughout the gland. Strands of fibrous tissue run through it from the capsule and produce a sort of indefinite lobulation. More striking, however, is the alteration in the alveoli. Instead of preserving a more or less uniform roundness, they are distorted into the most complicated forms, and their walls plicated and corrugated until the outline is an extremely irregular one. By many authors papillary outgrowths from the walls have been described, but Ehrich claims that these appearances are merely due to the irregular line of section of folds in the wall.

The cells are irregular in height and outline, and are often vacuolated and ragged, and contain more abundant fat globules than normal. There is much variation in the size of the alveoli, the distended irregular ones being frequently long drawn out and sometimes even communicating with one another, while others are small and so packed with cells that there is no real lumen. Mitotic figures are rare. Indeed Ehrich states that proliferation occurs only by amitotic division, and is not a prominent feature, but that the enlargement of the gland is largely due to the distention of the alveoli. The general trend of opinion, however, is toward the idea that there is a hypertrophy by cell proliferation.

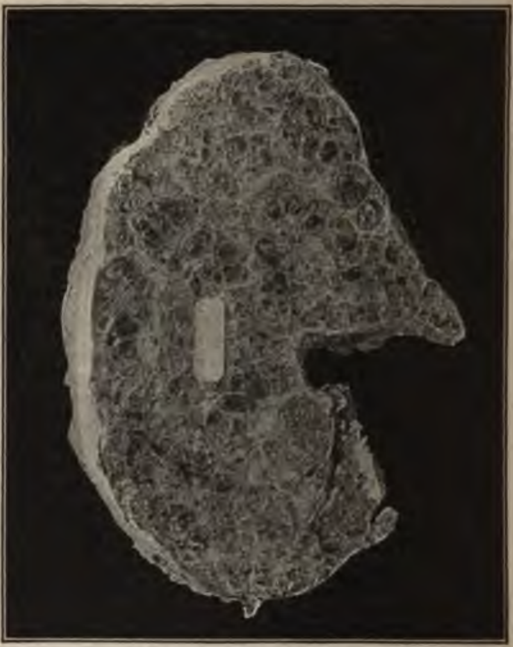

FIG. 5136.—Adenoma of Thyroid, or Colloid Goitre.

We may pass over the histological details of the process of secretion as observed in these cases by Farner, Ehrich, Haemig, and others. Suffice it to say that while in some cases the process of secretion seems active enough, and the alveoli are filled with a stainable colloid material, in the majority the secretion of this stainable colloid is not evident, the cells have become high and vaculated, and whatever secretion there is, is of the non-staining or chromophobe type of Andersson. The alveoli in these cases are empty of colloid, and contain only the débris of cells and fine ragged strands of granular material.

As to the removal of the colloid material from the gland there is still some doubt. Many authors have described the presence of a material staining like colloid in the lymphatics and interstitial spaces, while others have even declared its presence in the veins and arteries. Thus Farner[12] explains the lack of colloid in the follicles by the rapidity of its export. Ehrich, however, with right, suspects that the colloid-like substance in arteries and veins is merely the coagulated serum. Indeed he denies that any secretion escapes from the gland, and thinks the whole process a retrogressive one. Support is lent to Ehrich's views by the work of Oswald (*Virchow's Archiv*), who finds a decreased percentage of iodin in the thyroid in exophthalmic goitre, and considers the change a decrease in functional activity.

There is no statement in the literature as to any changes in the parathyroids in this affection, but an enlargement of the thymus is fairly constant, and in most of the cases a swelling of the cervical lymph glands has been observed. In a case recently dissected at the Johns Hopkins Hospital the hæmolymph glands in the neck were especially prominent.

e other organs show, as far as is known, no con-
lesions. Askanazy has described certain degenera-
hanges in the voluntary muscle, but investigations
matory of his results seem not to have appeared.
IOLOGY.—Several distinct theories as to the etiology
disease have been proposed, but they all fail to
nt satisfactorily for all the symptoms.
ording to one, which has been defended by Bu-
exophthalmic goitre is a general neurosis in which
ychic and vaso-motor functions are predominantly
d; but constant changes in the thyroid cannot be
ned on this idea.
ius is the chief defender of the theory of hyper-
lization, in which the thyroid forms the starting-
or all the symptoms. Certain authors have shown
pleasant symptoms—flushing, tachycardia, etc.—
llow the excessive administration of thyroid ex-
normal animals, and it has been conceived that
disease the enlarged thyroid is in a state of great
ry activity, pouring into the lymphatics far more
cretion than normal, and thus bringing about the
eristic symptoms. This view seems further sup-
by the results of surgical extirpation of part of
nd—the relief of the symptoms being frequent.
the symptoms can be produced by injection of
extract into normal animals, however, nor can
e symptoms of exophthalmic goitre be relieved
rpation of the active gland. For example, the
almos can neither be produced by thyroid ex-
r always relieved by thyroidectomy. There is
favor of this theory, but also several arguments
to it are difficult to answer. The disease is con-
o be a sort of general antithesis to the condition of
ma, which we know to be due to loss of the thy-
hence again the idea that such a reversal of the
s of myxœdema must be due to hyperthyroidi-
But histologically we cannot say with certainty
gland is secreting actively. Indeed, of the usual
e see little or nothing at all. The theory fails
n several important symptoms. The results of
tion for extirpation of part of the gland are not
good, and indeed not especially better than the
d and regular régime alone; and finally cases of
lmic goitre in combination with myxœdema
described—a condition which must directly
and disprove the theory of hyperthyroidiza-

thinks that the enlargement of the thyroid, and
st of the other symptoms, are due to the arte-
emia, but he fails to explain this itself.
s theory of a lesion in the corpora restiformia
count of the inconstancy of such a lesion.
a theory has been based upon the effect upon
f stimulation of the cervical sympathetic, as-
exophthalmic goitre, or at least many of its
to a lesion of the sympathetic. Now it was
ve that lesions of the sympathetic are by no
tant or even common, but the theory is not
pon the face of it for the following reasons:
the sympathetic causes pallor of that side of
traction of the eye, and narrowing of the
le stimulation causes a flushing of the face,
that side, protrusion of the eyeball, widen-
palpebral fissure, and dilatation of the
se symptoms of exophthalmic goitre might
rrespond with the results of a constant stimu-
e sympathetic, but even then the pupillary
s are absent in exophthalmic goitre, while
e most striking consequence of stimulation
.

e of the exophthalmos has given rise to much
this connection. It is by no means proven
to distention of retrobulbar vessels; nor can
that it is due to stimulation of the sympa-
ps by pressure of the enlarged thyroid, for
he goitre influences it very little. Protru-
e-ball is, however, not impossible to the nor-
al, and experiments of Filehne [13] and Durdufi [14] have shown that irritation of the corpus restiforme will produce exophthalmos even after the sympathetic is cut through. So also Kotschanowski [15] claims that it may be produced by stimulation of certain anteriorly placed cortical centres.

The theory of sympathetic irritation, being as it is without anatomical basis, explains only haltingly a few of the symptoms. It is impossible to make the lack of pupillary change agree with this conception, and the general tremors, general sweating, and vaso-motor disturbances, as well as the metabolic disorders and psychical symptoms, are not explained at all by such a theory.

Recent experimental work upon the thyroids and parathyroids seems to promise some light upon the subject. Briefly stated it has been found (Moussu,[16] Vassale and Generali,[17] Schiff,[18] and Gley [19]) that extirpation of the thyroids produces certain disturbances of nutrition which lead to the condition of myxœdema or cachexia strumipriva, while extirpation of the parathyroids leads, and in a far shorter time, to the death of the animal from symptoms of violent poisoning of the central nervous system—tetanic convulsions, dyspnœa, etc.—and that the tetany, which was previously ascribed to the removal of the thyroids, is really due to the simultaneous removal of the parathyroids, which are closely associated with them. Certain changes in the thyroid are said to occur after parathyroidectomy, and the tetany so produced is ameliorated by the removal or partial removal of the thyroids.

Slight exophthalmos sometimes occurs in the animals from which the parathyroids have been removed, and altogether the symptoms are rather suggestive of those of exophthalmic goitre. The suggestion has therefore been made (Gley, *British Med. Jour.*, 1901, September 21st), and is now being put to the proof, that possibly the development of this disease depends upon some lesion which destroys the parathyroids, and that it is nothing more than a long-continued parathyroid insufficiency. Indeed, one promising but incomplete attempt at the relief of the symptoms by parathyroid therapy has been made by Moussu.[20] As stated above, there appears to be but a very meagre description of the parathyroids in exophthalmic goitre in the literature (Benjamin's, "Ziegler's Beiträge," Bd. xxxi.), but in several cases which have recently occurred in the Johns Hopkins Hospital it was found possible to isolate parathyroids in four, although the glands were small, degenerated, and sclerotic. In a fifth and fatal case no parathyroid tissue was found at autopsy. It can readily be understood on this theory that the cases of combined myxœdema and exophthalmic goitre offer no difficulties. They are readily explained as cases in which the destruction of the thyroid produces the myxœdema, while destruction of the parathyroid independently produces the exophthalmic symptoms.

The theories as to the etiology are thus as yet not entirely satisfactory, although the last mentioned seems at least to offer some promise.

COURSE OF THE DISEASE; PROGNOSIS; TREATMENT.—The disease runs sometimes a very rapid course, terminating fatally after an illness of a few days only. In most instances it drags on for years and may end in recovery. The prognosis indeed is by no means very unfavorable, and a considerable proportion of the cases get quite well. There have been cases reported in which some sudden emotional shock is followed by intense symptoms, such as have been described, which after a short time disappear completely. In the cases in which the most intense symptoms are developed, however, and in which the clinical picture is complete, recovery without surgical interference is rare. The greatest variety of procedures has been employed in the attempt to cure these cases. From the medical point of view none are very satisfactory. Rest in bed, freedom from emotional disturbances, and the regular régime of the hospital seem to afford great relief in many cases, and are extremely important in the cure. The tachycardia is apparently not influenced by digitalis, although strophanthus is said to have some effect. Ergot and belladonna have been warmly recommended by some authors, and may do some good. Electricity, too, applied to the spine and peripheral nerves has been advocated by Erb and others

Based on the remarkable results obtained by the administration of the thyroid gland in myxœdema numerous cases of exophthalmic goitre have also been treated in this way regardless of the theory of hyperthyroidization, but the effects have been either actually harmful or entirely negative. The cases in which thyroid therapy has produced untoward results have therefore been brought forward as a strong support of the idea that the thyroid is already secreting too profusely, and thereby causing the symptoms.

From the fact that the thymus is usually found enlarged in exophthalmic goitre extracts of thymus have been given in these cases, sometimes with remarkable temporary results, but without any permanent advantage to the patient. In the case referred to above, which occurred in the Johns Hopkins Hospital, administration of the thymus extract reduced the pulse rate at once from 200 per minute to normal. When it was discontinued the pulse rose again to 200, and was again brought to normal by the thymus extract. After a time, however, its effect disappeared, and the pulse rate remained high until the death of the patient. In another case there occurred a remarkable reduction in the size of the goitre during its use. Since the parathyroid lies embedded in the thymus in the ox and certain other animals, it seems possible that it may be included in the extract manufactured from the thymus of these animals and may be responsible for the above results.

It was stated above that one attempt has been made to influence the symptoms by parathyroid feeding, and indeed the great amelioration following its use seemed very promising. The patient, however, died of tuberculosis before any definite result was attained. It is quite difficult to procure the glands in sufficient quantity for such treatment, but as soon as a parathyroid extract is on the market, it will be possible to give this remedy a thorough trial.

Quite recently Lanz,[25] Möbius,[21] Goebel,[22] Schultes,[23] and others have proposed and carried out a treatment which is based on other principles, and which they claim to be very successful. On the idea that the thyroid is concerned in the neutralization of poisons produced elsewhere in the body, and that in exophthalmic goitre it is so active that not only does it neutralize these poisons but further poisons the organism by the excess of this antitoxin (!), these authors attempt to supply this overactive thyroid with poison for neutralization by injecting the serum of thyroidectomized sheep, in which supposedly much of the poison must have accumulated, or by feeding them on the milk of such thyroidectomized animals. The chances for fundamental error in the conception of this treatment seem very great, for it is by no means proven that in exophthalmic goitre the thyroid is overactive; nor, on the other hand, is it proven that the function of the thyroid lies in the neutralization of poisons elaborated elsewhere.

In recent years the surgical treatment of exophthalmic goitre has become very prominent. It also is based upon the idea that the enlarged thyroid is overactive in pouring its secretion into the lymphatics, and the cases are therefore subjected to the partial extirpation of the thyroid.

The operation is a serious one, hemorrhage being very difficult to control. The patients do not take the anæsthetic well and many have died on the table.

Of late years, however, many of these operations have been performed under a local anæsthetic. Kocher[24] has reported fifty-nine cases, in which the results have been on the whole very satisfactory, often with almost complete or complete relief of all the symptoms. Usually the exophthalmos persists or disappears gradually, and often the improvement in the symptoms does not immediately follow the operation, but appears later. Much anxiety has been expressed from time to time as to the dangers of allowing the escape of thyroid secretion into the wound during such an operation, and the fever which sometimes follows the operations has been ascribed to this. Lanz,[25] however, has shown experimentally that the most violent crushing and laceration of the thyroid which is then left *in situ* is not usually followed by any rise in temperature nor by any special untoward symptoms.

Ehrich has reported eight cases of operative extirpation of part of the thyroid in exophthalmic goitre, but is far less enthusiastic about the results. Many of these were not relieved, or suffered a recurrence of all the old symptoms after a temporary relief. He thinks that on the whole the good results are due mainly to the regular régime of the hospital for a time after the operation and to the suggestive effect of the operation.

In some instances merely ligation of the vessels of the thyroid has been performed, often with favorable results.

In none of these operations has any attention been paid to the condition of the parathyroids.

Operations for the section or removal of the cervical sympathetic trunks have been performed (Jaboulay,[26] Balacescu[27]), with results which they claim to be quite as good as those obtained by the extirpation of the thyroid.

A definite opinion as to the value of these different methods of treatment must, however, be reserved until our knowledge of the results is more extended.

William G. MacCallum.

EYEBALL, ENUCLEATION AND EVISCERATION OF.—I. ENUCLEATION.—By enucleation is meant a shelling of the eyeball out of Tenon's capsule with preservation of the relation between the conjunctiva, ocular tendons, and the other contents of the orbit.

History.—In 1841 Bonnet, of Lyons, first described and recommended true enucleation. The operation had been performed in a very crude manner by Bartisch, of Saxony, in 1583, by passing a sharp spoon behind the eyeball and thus gouging it out of Tenon's capsule. Bonnet's operation had the great merit of preserving the capsule of Tenon and disturbing as little as possible the soft parts of the orbit. It became justly popular. Like most surgical procedures it has been variously modified by different operators. During the past few years it has been greatly improved and its cosmetic effect enhanced by suturing the tendons of the four straight muscles to the conjunctiva.

Operation.—The following instruments are required: stop speculum, fixation forceps, toothed forceps, stra- smus scissors, strabismus hook, a strong pair of scissors rved on the flat for cutting the optic nerve, a needle- lder, fine curved needles, and black silk for sutures. general anæsthetic is advisable, although the operation ıy be performed under local anæsthesia.

The lids being held apart with a stop speculum, the ·geon incises, with strabismus scissors, the conjunctiva l adjacent fascia all around as close as possible to the neal margin, and dissects the same from the sclerotic far as the insertions of the tendons of the straight scles. The tendon of each straight muscle, beginning :h the internal rectus, is then, in succession, raised ɔn a strabismus hook and secured with a suture of ck silk, after which the tendon is severed with stra- nus scissors as close to the eyeball as possible. The erior portion of the eyeball being now free from all ıchments, may be dislocated forward by pressing the ɔ speculum back. The curved enucleation scissors next introduced with the points closed and are pushed kward between the eyeball and the detached conjunc- until the optic nerve is felt. After the exact posi- of the optic nerve is found, it is included between blades and cut close to the sclerotic by one strong

The eyeball now readily protrudes and is held by fingers of the left hand, while the tendons of the two ue muscles and all adherent tissue are severed close ıe globe. A small ball of sterilized gauze is inserted ıe capsule of Tenon for the purpose of checking hem- ıge and of aiding the next step, the suturing of the ons of the straight muscles to prevent their retrac-

Each rectus tendon is now drawn forward and fast- to the margin of the conjunctiva by the same re which was inserted just before the division of the ɔn. The sterile gauze should now be removed, the ins of the conjunctiva and capsule of Tenon united several interrupted sutures, and a dry antiseptic ing applied. Both eyes should be bandaged for ty-four hours and the patient kept in bed for a le of days. The socket should be washed out once with physiologic salt solution until after four or five when all dressings may be discontinued.

: technique of the operation, as above described, ·en varied by different operators. The most impor- ariations relate to methods of preparing the stump enucleation, which will best secure motility of the ·sis and furnish cosmetic results. The following ıd has been brought forward by G. F. Suker: removing the eye, the severed tendons of the recti ·s are brought together by means of the silk guides ıtured one to the other with either catgut or silk. ɔnjunctiva from above and below is then brought ıe muscle stump and sutured with a continuous or ıpted suture. H. V. Wurdemann, who was one of ıt ophthalmologists to point out the advantages of a ly prepared stump, makes a pouch suture by ıg the needle along the cut edges of the divided ctiva and Tenon's capsule. In passing the recti s, each one is picked up on the needle.

chmidt has suggested the following method: Each of the recti muscles is secured by a catgut suture, ter division, is fastened to a slit made in the con- a over the site of the tendon's insertion. The e edges of the conjunctiva are then brought to- with a continuous suture.

tley Smith has described the following method of g the tendons to the conjunctiva: A narrow hori- fold of the conjunctiva over the internal rectus is l up so as to include the subjacent connective tis- muscle, and a black silk thread is carried through ructures by means of a curved needle. The sut- hen tied firmly but not too tightly. A second s applied in like manner to the external rectus. per and lower recti may be treated in the same ıt this is of less importance. The enucleation is rried out and the conjunctival aperture may or : be closed by one or more vertical sutures.

Complications and Accidents.—Hemorrhage, occasionally severe and persistent, may occur during the operation or later. In enucleating an inflamed eye, there is always a good deal of hemorrhage, particularly where there has been extension of inflammation into the surrounding tissue. The hemorrhage in this case is beneficial. Hemorrhages following an enucleation may require repeated packing of the orbit with antiseptic gauze. Occasionally a secondary hemorrhage occurs, when the dressings must be removed and the orbit packed with gauze. In these cases the tissues of the orbit may become greatly swollen from infiltration with blood. In chronically inflamed eyes, dense adhesions, binding the conjunctiva and its underlying fascia to the sclerotic and the tendons of the straight muscles, may be encountered. These cases often require a most careful dissection in order to expose the tendons, but by taking time and keeping the sclerotic always before him, the surgeon may perform the operation without accident. In enucleating an eyeball that has been perforated, or one soft from any cause, great care must be taken to remove it without leaving portions of the sclera and choroid behind. When an eyeball is enucleated because it contains a malignant growth, the posterior orbit should be carefully explored with the finger and probe before severing the optic nerve; and if a tumor is found, it should be removed along with the eyeball. As much of the optic nerve as possible should be removed with the globe. In very rare cases, enucleation has been followed by fatal meningitis, especially when performed on an eye within which suppuration was taking place. Up to 1900 G. E. de Schweinitz had collected fifty-two cases of fatal meningitis following enucleation, "thirty-three of which certainly—and a larger number probably—had followed enucleation for one stage or another of suppurative disease within the globe." The risk of a fatal termination from any cause after enucleation is about one in sixteen hundred. Meningitis after enucleation of a non-suppurating eyeball is exceedingly rare. In 1898 the Committee of the Ophthalmological Society of the United Kingdom could not find a single instance among 10,784 cases gathered from various sources.

Indications for Enucleation.—There are certain affections of the eye for the relief of which enucleation is demanded and cannot be replaced by any other operation. Enucleation is demanded in all cases of malignant tumor of the globe except in those rare cases of tumors which grow at the limbus and on the conjunctiva or iris. It is also required in cases of malignant tumors of the orbit which cannot be removed without sacrificing the eye. Enucleation is to be performed in those cases of sympathetic ophthalmitis in which the sight of the exciting eye has been lost. It is also demanded in the cases of eyes so injured that they are likely to excite sympathetic ophthalmitis, if two weeks or more have elapsed since the injury; for while enucleation cannot prevent all cases of sympathetic ophthalmitis, it is the operation which holds out the best chance for the prevention of the disease.

On this account enucleation should be performed in the case of an eye with a wound so situated as to involve the ciliary region, and so extensive as to have destroyed the sight or to make its ultimate destruction by iridocyclitis reasonably certain. It is also indicated in the case of an eye with a wound in the ciliary region, complicated by severe inflammation of the iris or ciliary body, even if sight is not destroyed; or of an eye containing a foreign body, which judicious efforts have failed to extract, and in which severe iritis is present, even if sight is not destroyed. Enucleation is also to be performed in the case of an eye in which the wound has involved the cornea, iris, or ciliary region, and in which persistent sympathetic irritation in the fellow-eye has occurred, or in which there have been repeated relapses of sympathetic irritation; in the case of an eye long blind from injury which has become red and painful; in cases of painful phthisis bulbi, and in those in which the choroid has undergone calcareous changes. Enucleation is also indicated in cases of grave traumatisms in which the sclerotic coat is extensively lacerated.

Other affections, believed by many surgeons to require enucleation, but for which one of its substitutes may be performed, are: Eyes so injured that they are likely to excite inflammation, which have come under observation within two weeks from the time of injury; painful glaucomatous eyes, unrelieved by sclerotomy; chronic painful iridocyclitis; panophthalmitis without involvement of the orbital tissues. In extreme old age enucleation is to be preferred on account of the recovery being smoother and shorter than is usually the case in evisceration. The same consideration may decide both the surgeon and the patient in favor of enucleation in the case of a workingman, especially where the cosmetic results are not important.

The Relation of Simple Enucleation to the Wearing of an Artificial Eye.—The artificial eye may be fitted as soon as the wound is entirely healed, in the second or third week. The following rules have been adopted by the Moorfield Ophthalmic Hospital, London, for the guidance of patients wearing artificial eyes:

To put the eye in: Place the left hand flat upon the forehead, and with the two middle fingers raise the upper lid toward the eyebrow; then, with the right hand, push the upper edge of the artificial eye beneath the upper lid, which may be allowed to drop upon the eye. The eye must then be supported with the middle fingers of the left hand while the lower eyelid is raised over its lower edge with the right hand.

To take the eye out: The lower lid must be drawn downward with the middle finger of the left hand; and then, with the right hand, the end of a small pin must be put beneath the lower edge of the artificial eye, which must be raised gently forward over the lower lid when it will readily drop out.

Patients very soon become expert in introducing or taking out artifiical eyes and do not require the aid of a pin in removing them. The artificial eye must be removed every night and carefully cleansed. In selecting an artificial eye for use after enucleation the various forms of glass eye, proposed by Snellen, are decidedly superior to the older form of a simple shell. The cosmetic effect of the Snellen reformed eye after a well-performed enucleation is so good that many surgeons believe that it renders unnecessary the operations which have been brought forward as substitutes for enucleation.

Implantation of an Artificial Globe in Tenon's Capsule after Enucleation (Frost-Lang Operation).—The eyeball is enucleated in the ordinary manner, and after all hemorrhage has been arrested an artificial sphere is inserted within Tenon's capsule for the purpose of forming a more prominent stump and giving it greater activity and mobility. Glass and gold spheres are commonly employed, more rarely celluloid or silver balls. Sterilized paraffin injected into Tenon's capsule has been advocated by Ramsay and Oatman. The capsule and conjunctiva are sutured over the artificial ball with silk sutures, the tendons of the straight muscles having first been secured in the manner described under enucleation. The following method of performing the operation has been introduced by C. A. Oliver: "The conjunctiva around the entire corneal limbus is freed from the globe and dissected sufficiently far back so as to expose the tendons of the four recti muscles. The tendinous extremities of the muscles are made ready for separation from the globe. A half-curved needle with its point directed toward the corneal border and holding a long piece of catgut thread is carried directly through the belly of the internal or the external rectus muscle and brought out of the tendon of the muscle just behind the remaining attachment to the globe. The muscle thus secured is cut loose from the globe just as in ordinary tenotomy. The catgut thread is drawn through as far as practicable, and a sufficient length of the strand of gut is left untouched to allow a loop broad enough for free manipulation between it and the eyeball. The needle is carried over to the opposite side of the cornea, and with its point directed away from the cornea is made to transfix the tendinous belly of the other lateral muscle, which is secured and freed from its attachment to the eyeball. The vertically placed muscles are dealt with in a similar manner. The four recti muscles are thus freed from their attachments to the globe, and each pair of muscles secured by a loose sling, that can be tied the moment this becomes necessary. Working in between the broad loops of catgut, attached to the ends of the muscles that are held apart by an assistant, the eyeball is enucleated. The cavity previously occupied by the globe is thoroughly cleansed and a water-tight glass ball, about three-fourths the size of the normal eye, is dropped into place. The ends of the lateral recti muscles, which are held by the lower and first-placed thread, are neatly trimmed and sutured together. The same is done with the two ends of the vertical straight muscles. The circular opening made by the cut edges of the conjunctiva is made into a lozenge by a couple of horizontal snips, and is carefully brought into linear apposition by a series of silk threads. The operative field is covered by a gauze protective bandage upon which ice compresses are placed."

Indications and Contraindications.—An articifial globe may be implanted in Tenon's capsule whenever it is necessary to remove the eyeball completely, except in cases of malignant disease, sympathetic ophthalmitis, suppuration within the globe, and in extreme old age.

Complications.—These are: Hemorrhage, orbital cellulitis, sympathetic irritation, tearing out of the stitches from sloughing with escape of the artificial ball, and late cicatricial contraction of the orbital tissues, causing extrusion of the ball. Adolph Bronner has lately advocated the insertion of a glass ball with a hole through the middle, which is covered in with glass so as to keep the ball air- and water-tight. By a somewhat elaborate method of stitches, this is held in, and he claims is less liable to be thrown off than a simple globe.

After-Treatment.—The eye should be dressed with a dry antiseptic dressing and both eyes bandaged. Care should be taken to avoid using pressure bandages. If much reaction follows, it is advisable to employ an ice bag for the first twenty-four hours. The patient should be confined to bed for four or five days.

An artificial shell—the ordinary or Snellen's—can be inserted at the expiration of a month or six weeks. The cosmetic result is apparently no better than that which is obtained by a properly performed enucleation and the wearing of a Snellen reformed eye.

Implantation of a Piece of Sponge in the Orbit after Enucleation.—This procedure has been suggested by Claiborne, of New York, and Belt, of Washington, for the purpose of gaining a more prominent stump and an improvement in adapting prothesis. The method has never come into general use on account of the prolonged convalescence and the late results being no better than those of a well-performed enucleation.

II. Evisceration.—In this operation the cornea and entire contents of the eyeball are removed, the sclera alone remaining. This procedure was first proposed by Alfred Graefe, in 1884, to prevent meningitis after the removal of eyes affected with panophthalmitis.

The instruments required are eye speculum, fixation forceps, a Graefe or Beer knife, strabismus scissors, sharp spoon, needle-holder, small curved needles, catgut and silk sutures.

Operation.—After general anæsthesia the speculum is introduced and the eyeball steadied by grasping with fixation forceps a fold of conjunctiva near the corneal margin. The eye is then transfixed just back of the corneal limbus with a Beer or Graefe cataract knife, which is made to cut its way out at the upper or lower sclerocorneal border, so as to include the corneal and about 1 mm. of the scleral margin in the flap. The flap is now grasped with forceps and the remainder of the incision completed with scissors. The next step is to remove the entire contents of the sclera, great care being taken that nothing is left behind, especially none of the choroidal

dressing after evisceration should be a light, dry,
tic one. The patient should remain in bed at least
five days with both eyes bandaged. Cold appli-
should be used for a day or two to keep down the
. The sutures may be removed in from three to
ys. The recovery is commonly less smooth than
m simple enucleation, and considerable pain with
and swelling of the surrounding tissues may fol-
operation. The operation is often performed
e inflammatory process is already high, and when
tal tissues are secondarily involved. No cases of
itis have occurred. Sloughing of the sclera has
ted, and a painful stump may be one of the com-
ns.

tions for Evisceration.—The operation having
troduced by Alfred Graefe as a substitute for
tion in cases of panophthalmitis, it very naturally
l that this affection at once took front rank as an
on for evisceration. Graefe had lost two patients
from meningitis following enucleation, and al-
l surgeons in Germany, where his influence was
, feared to enucleate an eye during the height of
halmitis. Mauthner tells us that this feeling
far that a German operator even excused himself
ng enucleated two panophthalmitic eyes with the
lts, because he did not know at the time what
ad said on this point. Writing in 1878, Mauth-
hically describes his own feelings on the subject.
ally," he says, "I stand in awe of Graefe's advice
operate if the panophthalmitis is distinctly pro-
. I have never enucleated an eye under such
ances, and I doubt if I shall ever make up my
do so. The terrible apparition in von Graefe's
presses me so deeply that at the very sight of an
state of panophthalmitis, and the thought of
ng it, the dread of a fatal result is conjured up
e."

thstanding his fears, Mauthner apparently had
ve doubts regarding the justifiability of abstain-
operation, and allowing suppuration within the
continue without interference. Meantime, the
oculists, under the leadership of Critchett, con-
enucleate during panophthalmitis as compla-
though Graefe had never warned against it, and
scussing a fatal case reported by Nettleship in
l that this was the first fatal occurrence among
housand enucleations done at Moorfield Oph-
Hospital. American ophthalmologists have
d much attention to panophthalmitis as a con-
ion for enucleation, and Noyes, in a paper read before the American Ophthalmological Society in 1889, on "Enucleation during Panophthalmitis," says: "We are certainly justified in performing the operation notwithstanding the warnings and alarming declarations of Prof. Alfred Graefe."

Although the risk of a fatal termination after enucleation during panophthalmitis is so small that the operation may be performed almost with impunity, there can be no doubt that when the purulent inflammation has extended to the orbital tissues evisceration is the safer plan. Staphylomas of the cornea, especially when they occur in children, are well suited to evisceration. Painful, blind, glaucomatous eyes, or eyes blind from chronic, non-traumatic iridocyclitis, may also be safely eviscerated. This operation will also be indicated in the cases of eyes injured in the anterior portion of the globe, when all thought of recovery under conservative treatment has been abandoned within two weeks of the time of injury.

Contraindications.—These are malignant disease, sympathetic inflammation, sympathetic irritation, phthisis bulbi, ossified choroid, and foreign bodies penetrating the orbit.

The Relation of Simple Evisceration to the Wearing of an Artificial Eye.—A Snellen artificial eye may be inserted during the third or fourth week. The ultimate cosmetic effect is no better than, and in some cases not so good as, that obtained after enucleation performed according to modern technique.

EVISCERATION OF THE EYEBALL, WITH INSERTION OF AN ARTIFICIAL VITREOUS; MULES' OPERATION.—Mr. Mules, of Manchester, England, in 1886, modified the operation of simple evisceration by the introduction of a glass ball into the cavity of the sclera. The operation is performed as follows: After general anæsthesia a stop speculum is introduced and the conjunctiva freed all around from the corneal margin and dissected back as far as the equator of the eyeball, without disturbing the relations of the muscles. The cornea and 1 mm. of the scleral margin are then removed in the manner described under evisceration. A triangular portion of the sclera, above and below, should also be removed to facilitate the introduction of the artificial vitreous, and in order that the coaptation of scleral edges over the same may be perfect. Next, the contents of the globe should be removed in the manner described under simple evisceration, and all hemorrhage arrested by packing the scleral cavity with dry sterile gauze, or gauze soaked in hot sterile water. The next step is the introduction of a thoroughly sterilized artificial vitreous, usually of glass or gold. A sphere of such size that it can be easily inserted within the scleral cavity is selected. The introduction of the sphere is best effected by means of a special instrument designed for the purpose by Mr. Mules. The margins of the scleral opening are then united vertically by means of interrupted silk sutures, and the conjunctival opening is closed by another line of sutures placed at right angles to the sclerotic line of closure. The greatest care must be observed to secure absolute asepsis during the operation and at all subsequent dressings. A bandage which does not make much pressure should be adjusted over a dry antiseptic dressing. The fellow-eye should also be bandaged and, unless for special indications, the dressing should not be removed for forty-eight hours. Should there be decided reaction, iced compresses should be applied. The patient should be kept in bed for three or four days and both eyes bandaged until there is firm union of the wound. The superficial sutures should be removed on the third day, the scleral suture remaining permanently.

Some surgeons perform the operation according to a different technique from that described above. Gifford eviscerates through a horizontal incision in the sclerotic according to his special method previously described, and implants the artificial globe through this opening without removing the cornea. Some operators close the sclerotic and conjunctival wounds with the same sutures.

The purse-string suture is used by some of the best operators for closing the scleral opening, after which the conjunctival wound is closed with another purse-string suture. Some operators advise the removal of the conjunctival suture at the end of forty-eight hours. Mr. Collins, of Moorfield Hospital, believes that many failures of this operation are due to allowing the superficial suture to remain too long.

Indications.—The chief indications for this operation, as given by de Schweinitz, are: Staphyloma of the cornea and sclera, ruptured or injured eyeballs when the sclera is not too much lacerated and when the accident is of recent date, absolute glaucoma, buphthalmos and non-traumatic iridocyclitis.

Contraindications.—The following contraindications are enumerated by the same authority: Suppuration of the eyeball; morbid growths; much shrunken eyeballs, the contents of which have undergone bony or calcareous change; sympathetic ophthalmitis; sympathetic irritation and pathologic conditions of the eyeball which are likely to produce either of the last-named affections; extensive injuries of the eyeball, with much bruising and laceration of the sclera; dacryocystitis and ocular conditions demanding enucleation or its equivalent in very old persons.

Accidents and Complications.—The operation may be followed by excessive reaction manifested by marked swelling of the lids and chemosis of the conjunctiva, headache, nausea and vomiting, and elevation of temperature. It is probably always caused by faulty technique, as imperfect asepsis, failure to arrest hemorrhage, the use of strong antiseptics and undue dragging upon the optic nerve. Sloughing of the sclera and consequent cutting out of the stitches occur in about eight per cent. of all cases. Extrusion of the artificial vitreous within the first week or at a much later period took place in seventeen per cent. of the three hundred and sixteen cases in the hands of thirty-three different operators, tabulated by de Schweinitz. The chief cause of escape of the artificial globe is failure of the edges of the scleral wound to unite. Another important cause of the throwing-out of the glass ball is that it may have been too large or too small for the scleral cup. An irritable and painful stump requiring removal has been met with as a complication following the operation. Sympathetic inflammation has been met with as an unfortunate complication in a number of instances. While in most cases it was due to the seeds of the disease having been planted before this operation was performed, it seems in several instances, as in the case reported by Carrow, to have been directly due to the operation itself. The report of the committee of the Ophthalmological Society of the United Kingdom in 1898 contains the following statements: "We have not found a record of any case of sympathetic ophthalmitis following evisceration without the implantation of an artificial globe, and we have collected records of five cases of sympathetic ophthalmitis after the operation of evisceration and the introduction of an artificial globe into the emptied sclerotic." Sympathetic irritation has been met with on rare occasions and required the removal of the stump.

Special Advantages with Relation to the Wearing of an Artificial Eye.—After a successful Mules' operation the motility of the stump and artificial eye is usually better than that after enucleation, the implantation of a ball in Tenon's capsule, or simple evisceration. The cosmetic result is extremely satisfactory, for the natural contour of the lids being preserved, there is none of the shrunken appearance so often presented by artificial eyes. The absence of accumulations of mucus and tears adds to the patient's comfort and satisfaction. The high percentage of failures, due to extrusion of the artificial vitreous, must be greatly reduced before the operation can take a permanent place in ophthalmic surgery. At the present time the prevalent feeling among ophthalmologists regarding the operation of Mules is one of disappointment.

Edmund W. Stevens.

FACIAL HEMIATROPHY.—(Synonyms: Unilateral atrophy of the face; Progressive facial hemiatrophy; Progressive laminar aplasia; Facial trophoneurosis; Facial circumscribed atrophy.)

The first known description of facial hemiatrophy is that by Parry, written in 1825. In the year 1846 Romberg described the condition more definitely and called it a trophoneurosis.

The disease consists of an acquired circumscribed atrophy of the face. The atrophy, involving soft tissues and bone, follows a chronic course, and finally becomes spontaneously stationary.

Something over one hundred authentic cases have been reported.

ETIOLOGY.—The disease belongs to the period of youth. Practically all of the reported cases began before the thirtieth year. Women are more frequently affected than men, in the proportion of about two to one. It does not appear that nationality, station in life, or heredity has any influence on the development of the syndrome. In the reported cases it has followed typhoid fever, measles, scarlet fever, syphilis, and other infectious diseases. It has been observed in the course of multiple sclerosis, syringomyelia, multiple exostoses of the face and head, scleroderma, insanity, epilepsy, and hysteria. It is not unusual for the patient to ascribe it to blows or other injuries to the face. In a number of cases the early symptoms have been those of a severe trigeminal neuralgia. In one case which I saw there had been a severe malarial infection one year before.

PATHOLOGICAL ANATOMY.—Various theories have been advanced in regard to the lesions which may produce facial hemiatrophy. Disease of the sympathetic nerves, of the peripheral distribution of the fifth cranial nerve, of the Gasserian ganglion, of the nuclei of the fifth nerve, and of the cortex of the cerebrum have in turn had their theoretical advocates. The principal anatomical evidence rests on the findings in Mendel's case; this was a woman who for fifteen years had suffered from left facial hemiatrophy. The autopsy showed the epidermis normal except for a moderate degree of thinning, the connective tissue was diminished, the blood-vessels were few and small, the fibres of the muscles were somewhat thinned without degeneration or nuclear changes, and the facial nerve was normal. In the trigeminus the connective tissue around and penetrating the nerve was much thickened. In many places the number of nerve

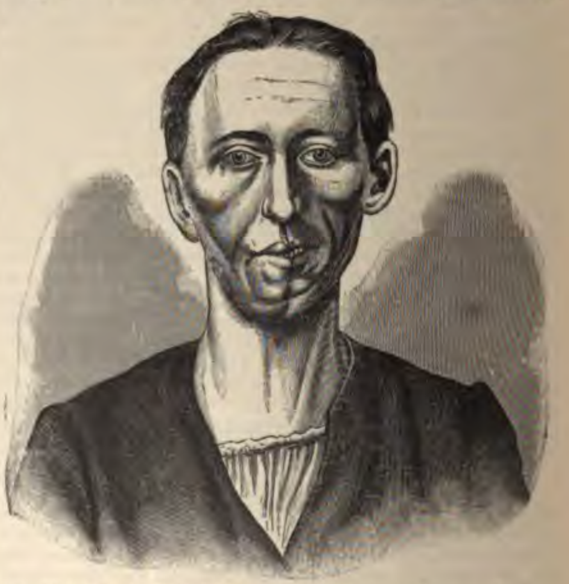

FIG. 5137.—Facial Hemiatrophy Beginning in a Woman Twenty-four Years Old. (After Frombold-Treu.)

res was diminished. Most of the changes were in the ond division of the nerve. There was also atrophy of descending root of the trigeminus and of the substan- ferruginea. Mendel believed that the facial atrophy s due to the proliferative interstitial neuritis of the tri- ninus. In this case there was also an atrophy affecting left upper extremity and some of the muscles of the ulder and back. To account for this Mendel found nterstitial neuritis of the musculo-spiral nerve and a inution in size and number of the cells of the anterior n of the cord at the level of the fifth cervical nerve.

he antecedent neuralgias of the fifth nerve point to as the site of the lesion. But how many severe neu- ias of this nerve have we not seen with no subsequent phy? Section of the posterior root of the trigeminus be attended by unilateral atrophy of the muscles of face, tongue, and bones of the face, and changes in amount and color of the hair. Operations on the erian ganglion have been said to be unattended by hic changes in the skin.

her autopsies in patients showing facial atrophy shown other lesions which take them out of the p of cases now under discussion. Such was Graff's which showed on autopsy a progressive muscular hy, and that of Jolly and Recklinghausen, in which ound a disseminated sclerosis of the brain.

IPTOMS.—Patients who develop facial hemiatrophy ly present themselves to the physician complaining euralgia in the distribution of the trigeminal nerve. this has lasted for several weeks or months the ial symptom of the syndrome appears. This con- n an atrophy commencing in the skin of the face. appears on the face a whitish spot which may soon lowed by other similar spots. These may extend hey cover half of the face, or may be limited to a area. Gradually these areas change in color to a ish-brown, while the skin becomes thin and stretched over the subcutaneous tissues. The ex- the atrophy may vary to a considerable degree. old-Treu indicates the varieties in his attempt to y them: (*a*) Typical cases involving one-half of ce. (*b*) Incomplete cases involving a portion of le of the face. (*c*) Double cases involving both f the face. (*d*) Cases in which other parts of the de of the body are involved. Following the atro- the skin there is a falling away of the underlying The fat may totally disappear, but at times is be replaced after the atrophic process has come to still. The frontal, malar, upper and lower jaw ay atrophy. The muscles supplied by the fifth ecome very thin, but their electrical reactions re- rmal and their function is not wholly destroyed, much weakened. The nasal cartilages usually less frequently the auricle is involved. The hair ead, eyebrow, and beard may change color, be- in, or fall out altogether on the affected side. nds of the skin are usually unaffected, but anidro- been noted as well as diminished lachrymal . The blood-vessels may show through the ed skin, marking it with an underlying network. gue and gums are frequently atrophied on the side. The tightening of the skin may interfere movements of the jaw. In the one case which bserved the mouth was drawn to the normal side eraction of the healthy muscles. Taste, touch, lectrical reaction are usually normal, even in the alf of the tongue. The trigeminal pain is occa- associated with spasmodic contractions of the or with fibrillary twitchings. As the atrophy the pain usually subsides. There may be par- or spots of hyperæsthesia (probably due to of the skin). Anæsthesia and changes in the re sense are exceedingly rare. The muscles by the seventh nerve are usually unaffected. orts a case in which the hearing was affected, on account of an atrophy of the tympanum. il may be contracted; or, as in Mailhouse's be dilated and fail to react to light or accommodation. The eyeball on the affected side appears prominent on account of the atrophy of the surrounding tissues.

COURSE AND PROGNOSIS.—The disease is insidious in its origin and slow in its development. It may continue to advance for two or three years, but all the cases terminate spontaneously, the majority at the end of one year, leaving an area of atrophy from which recovery is unknown. At the beginning one cannot predict the extent or duration of the atrophic process; it may involve a narrow furrow only, or half of the face, or even both sides of the face. As a rule a long and severe antecedent neuralgia suggests a less favorable prognosis. A cure or even an improvement in the atrophied parts is almost unknown, though some competent observers have claimed that in a few cases the face has filled out to a moderate degree; this was probably due to an increase in the fat. To the patient, however, cessation of the pain and muscular cramps is an improvement.

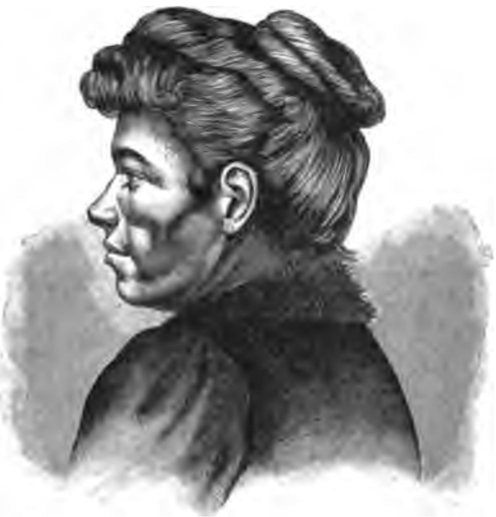

FIG. 5138.—Facial Hemiatrophy Following Pneumonia in a Woman Nineteen Years Old. (After Möbius.)

DIAGNOSIS as a rule is not difficult. The points particularly to be borne in mind are that the disease is an acquired one, developing before the thirtieth year. There is a change in the color of the skin followed by atrophy; the muscles usually affected are those supplied by the fifth nerve. Congenital asymmetry and forms of degeneracy should be easily differentiated. Confusion in cases of hemiplegia and the malnutrition of sympathetic paralysis is hardly possible. In Bell's palsy the muscles supplied by the seventh nerve only are affected. In these muscles there is a reaction of degeneration to the electric current, and tissues other than muscular are not involved. In the type of progressive muscular atrophy which first involves the face, the muscles alone atrophy; the skin, connective tissue, and bone are not affected. This disease, moreover, is progressive, and later other parts of the body are involved. Atypical cases of scleroderma may be confounded with facial hemiatrophy. The skin of scleroderma is usually harsh and infiltrated, while that of facial hemiatrophy is thinned.

TREATMENT.—At the present time we know of no measure that will limit the course of the disease. Neuralgias following abscesses of the teeth, tonsillitis and the infectious diseases should receive careful attention. Electricity and massage appear to have no influence on the course of the disease or in restoring the atrophied tissues. No drugs which have been tried have been proved of benefit excepting in so far that they control the neuralgic pains and muscular spasm. Sachs suggests thyroid extract. The value of this, as far as I know, has not been demonstrated. Section of the trigeminus, on the theory that the nerve stimulus is perverted, should be considered. Various contrivances have been devised for correcting the resulting deformity. Sachs has used a pad or rubber plate in the mouth. Eckstein has improved the appearance with subcutaneous injections of paraffin.

FACIAL HEMIHYPERTROPHY is a rare affection consisting of circumscribed enlargement of one side of the face. The process usually involves the skin, connective tissue, blood-vessels, muscles, and bone. In some cases the skin is harsh and rough, while the sebaceous glands are much hypertrophied and clogged with an abnormally thickened secretion of gummy consistence. The hair is often thick and coarse. In the case reported by Dana the bones were alone involved in the process; the soft tissues were not hypertrophied. The external ear may take part in the enlargement. Here either the cartilage alone or all the tissues may be involved. The hypertrophy may extend into the mouth implicating the gums, soft palate, and jaw. The hypertrophy may be limited to a part of the face on one side, or may extend somewhat across the median line.

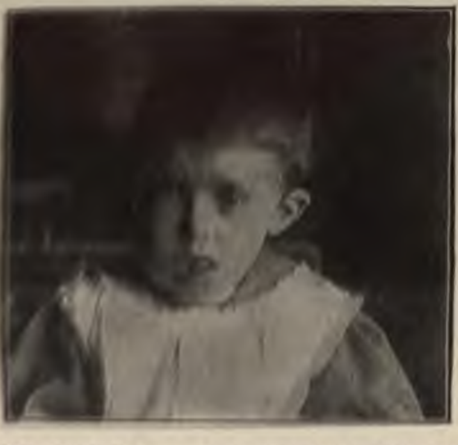

FIG. 5139.—Facial Hemihypertrophy in a Child. (After Sabrazès and Cabannes.)

But little is known of causes underlying the condition. Of the twenty-three cases collected by Sabrazès and Cabannes eighteen were congenital. In Schick's case the hypertrophy commenced in the second year with no known cause. In Berger's case there was an obstinate antecedent neuralgia of the fifth nerve. Montgomery's patient had brain fever when two years old. There was no neuralgia. When nine years of age the patient had an osteomyelitis of the left maxilla. About one year later hypertrophy first appeared in the gums of the left side. In Dana's case the patient was also affected with gigantism. It is probable that several distinct conditions have been described under the term of hemifacial hypertrophy. Among the theories advanced as to the etiology of the acquired cases may be mentioned irritation of the fifth nerve through its roots or the Gasserian ganglion, and chronic hyperæmia of vascular origin.

The enlargement may be first noticed in the bones, particularly about the orbit, giving the eyeball the appearance of being depressed in its socket. The bony hypertrophy gradually extends until the entire side of the head is included. In other cases (*e.g.*, Montgomery's) the process may begin in the soft parts, and the gums, skin, sebaceous glands, hair, connective tissue, muscle, and the bones become later involved. The enlargement of the blood-vessels may cause a reddening of the skin. The flow of saliva may be considerably increased.

There are few conditions which could be confounded with hemifacial hypertrophy. It has been suggested that it might be mistaken for hemifacial atrophy of the other side of the face; but anything more than a cursory examination could not fail to disclose the differences.

We know of no cases in which the hypertrophied tissues have been replaced by normal ones; but after a progression covering a period of several years it is probable that the condition may become stationary.

Treatment thus far has proved unavailing, either in limiting the course of the disease or in reducing the hypertrophy.

FŒTUS, DEVELOPMENT OF.—Our knowledge of the development of the fœtus was in an exceedingly fragmentary condition until Wilhelm His, the distinguished German anatomist, published twenty years ago his noteworthy "Anatomie menschlicher Embryonen." This was the first, and is to-day the most important work on human embryology. Previously there were isolated descriptions here and there of embryos of the first two months of pregnancy. Uncertainty as to the normal appearance often leads to the description of abnormal for normal ones, and the great difficulty in obtaining embryos of the first two months of pregnancy renders progress comparatively slow. The main sources of such material are from post-mortem examinations, operations, and abortions; so the human embryologist is thus dependent upon the courtesy of physicians and surgeons for his material.

Age.—In regard to the ages of embryos of the first two weeks much uncertainty exists. Length is not entirely reliable, owing to distortions and variability in size. In attempting to determine age from the last day of the last menstrual period as the date of conception, there is often the difficulty of inexact history. The following table indicates in a fairly accurate way the length and ages of embryos:

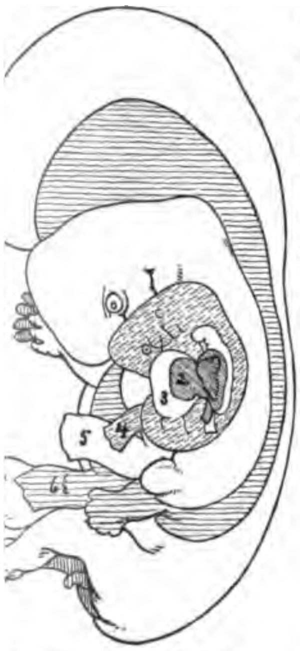
Age.	Length.	Age.	Length.
Two weeks	2 mm.	Three months	50 mm.
Three weeks	5 "	Four months	100 "
Four weeks	8 "	Five months	200 "
Five weeks	11-12 "	Six months	300 "
Six weeks	16 "	Seven months	370 "
Seven weeks	20 "	Eighth months	425 "
Eight weeks	25 "	Nine months	500 "

According to Mall their ages in days corresponds to the formula $\sqrt{100 \times (\text{length in millimetres})}$ for all embryos from 1 to 100 mm. long. Multiply the length of the embryo from vertex to the breech in millimetres by one hundred, and extract the square root, and the result will be its age in days. In embryos from 100 to 220 mm. long from vertex to breech their length in millmetres equals their age in days. Fig. 5140 indicates the relative sizes during the first eight weeks.

There are but few good collections of embryos in the world; the one at Leipsic and the one at Baltimore are the most important.

In development it is convenient to distinguish the three stages suggested by His. The stage of the ovum embraces the first two weeks; the embryonal stage from the third to the fifth week, during which time the characteristic embryonal features and the principal organs are established; lastly the fœtal stage, during which time the embryonal features change to those of the fœtus and full-term child.

The Ovum Stage.—There are no observations on normal ova of the first nine or ten days. It is evident a the material of the latter part of the stage of the m that there is an early and precocious development of the chorion and villi.



40. — Six Human Embryos from His' Standard Chart. ;ed three times. The figures cut indicate the ages of the o in weeks. 2 is His' embryo 3, embryo Lr.; 4, embryo A.; ryo C'; 6½, embryo XCI.; 8, o Wt. (After Mall.)

The youngest known normal ovum was described by Peters in 1899. It is ten to eleven days old and consists of a vesicle 3 × 1.5 × 1.5 mm. in size. A section through the entire ovum is seen in Fig. 5141. The vesicle is formed by the chorionic membrane, consisting of an outer layer of epithelial cells covered by numerous villi which are tact with the uterine ' the mother, and an ayer of mesenchyme. 'd to this inner layer at e is the small embryo, mm. in length. It is itly simple in structsisting of an epithelial cing the small amniotic ined by flat epithelial 'hich are continuous : epithelial cells of the On the other side of e is a layer of mesenand projecting from he yolk sac lined by nal cells. The pro-mbryo is surrounded nchyme continuous t lining the chorion, s with that between sac and epithelial

'. then, in the youngı ovum the so-called nary germ layers are present. From these at a later period various structures arise. From the epithelial layer develop the epidermis of the skin and its appendages, such as hairs, nails, sweat glands, etc., the central nervous system, and portions of the eye and ear, mouth and nose. From the middle or mesenchymal layer develop the skeletal, muscular, circulatory, and urogenital systems; and lastly from the inner or entodermal layer, which is here represented by the lining of the yolk sac, develop the alimentary tract (pharynx, œsophagus, stomach, and intestines), the trachea and lungs, liver and pancreas, and bladder.

The next important human ovum was described by Spee in 1896. It measures 7 × 5.5 mm. and the embryo within is 0.37 mm. in length. Its age is about eleven days. The chorion is covered with villi and lined with mesenchyme (see Fig. 5142). The embryo is attached at one side by a broad pedicle, the so-called belly stalk. The amniotic sac is small and is continuous with the epithelial plate of the embryo, as in the preceding ovum. The primitive streak is represented in this embryo by a slight groove along the centre of the epithelial plate. Mesenchyme separates the epithelial plate from the large

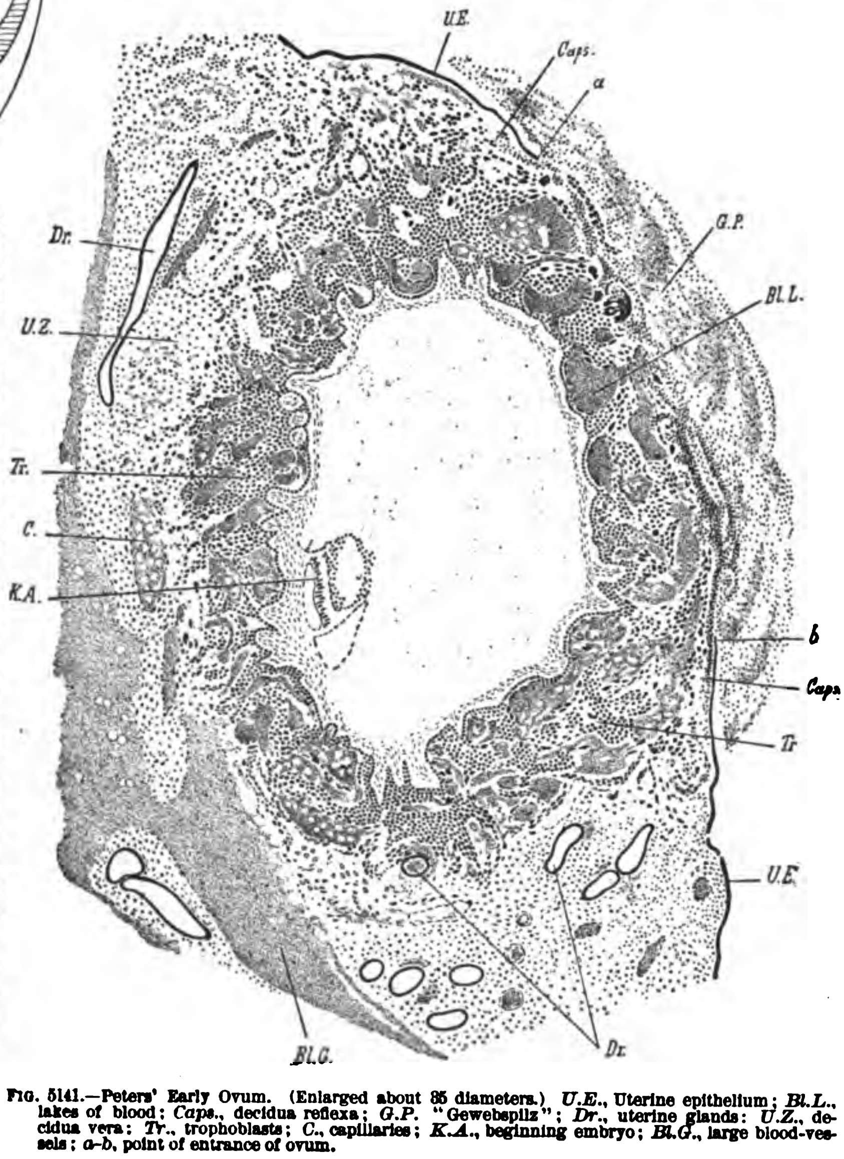


FIG. 5141.—Peters' Early Ovum. (Enlarged about 85 diameters.) *U.E.*, Uterine epithelium; *Bl.L.*, lakes of blood; *Caps.*, decidua reflexa; *G.P.* "Gewebspilz"; *Dr.*, uterine glands: *U.Z.*, decidua vera; *Tr.*, trophoblasts; *C.*, capillaries; *K.A.*, beginning embryo; *Bl.G.*, large blood-vessels; *a–b*, point of entrance of ovum.

yolk sac, and a small diverticulum of the sac projects into the mesenchymal pedicle, constituting the first trace of the allantois. We thus see that the embryo in this ovum, although about twice as long as the Peters embryo, shows very little advance in structural differentiation. Both are in the primitive streak stage.

Spee also described an ovum 10 × 8.5 × 6.5 mm. containing an embryo 1.54 mm. in length and about eleven and one-half days old. The chorion is covered by large branching villi, lined by mesenchyme, and attached at one side by a short pedicle is the embryo (see Fig. 5143). The primitive streak still persists, and near its anterior end the neurenteric canal has formed, thus connecting the amniotic cavity with the yolk sac. All traces of it are soon lost. More anteriorly still are traces of two longitudinal ridges, short distances on either side of the median line. These are the so-called medullary folds and are the first traces of a differentiation for the central nervous system. The allantois as in the preceding embryo projects from the yolk sac into the pedicle or belly stalk.

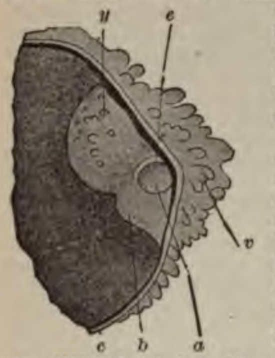

FIG. 5142.—Ovum Measuring 6 × 4.5 mm. (Enlarged about 10 diameters.) The left half of the chorion has been removed to show the embryo. *a*, Amniotic cavity; *b*, belly stalk; *c*, chorion; *e*, embryonic disc; *v*, chorionic villus; *y*, yolk-sac. (von Spee.)

Between this stage and the next one we shall consider, the embryonic plate changes from a flat discoidal structure to a somewhat cylindrical body by a bending ventrally of its lateral edges, to which the amnion is attached, thus gradually constricting the broad attachment of the yolk sac. At the same time the head and tail ends begin to project more and more, and the yolk sac is thus also constricted in an anterior posterior direction. Connecting pockets of the yolk sac remain at both the head and tail ends of the embryo to form the beginnings of the digestive tract. During this time the medullary folds have lengthened and grown toward each other, so as to meet in the mid-dorsal line, thereby enclosing a central canal, the beginning of the central canal of the spinal cord and the ventricles of the brain. In the next oldest ovum we are to consider, which was described by Eternod, there was an embryo 2.11 mm. in length. The medullary folds have not only met, but are fused for a considerable portion of their length to form the neural tube (see Fig. 5144). The head of the embryo now projects some distance beyond the constricted yolk sac, and on the ventral side of this head fold is a slight invagination of the ectoderm for the mouth. Between the mouth invagination and the attachment of the yolk sac the heart is in the process of development from two lateral tubes, which soon fuse together to form the simple tubular heart. The blood-vessels which have developed in the extra embryonic area and those that have developed in the body of the embryo have now become connected with the heart, and at its head end arises the ventral aorta dividing immediately into three pairs of branchial arches, which pass around the primitive foregut to unite beneath the medullary plate into the dorsal aorta. From the dorsal aorta are given off the omphalo-mesenteric and the umbilical arteries. The first veins to develop are those which accompany the first formed arteries, namely, the omphalo-mesenterics, connected with the yolk sac, and the umbilicals, connected with the allantois. Soon after these are formed the veins within the body of the embryo develop, the first ones being the anterior cardinals, or internal jugulars and the inferior cardinals, the latter draining the blood from the caudal portion of the body. An anterior and a posterior cardinal of each side unite to form the ductus Cuvieri. The two ducts, one on either side, pass transversely toward the median line and open into the sides of the sinus venosus. The omphalo-mesenteric veins coming from the yolk sac and the umbilicals from the allantois join the sinus venosus at a slightly earlier date than do the Cuvierian ducts. At a later stage we shall see how this primitive arrangement is modified to form the adult condition. The yolk sac in this embryo is somewhat constricted along its attachment, leaving pockets of entoderm connected with it that lie in the head and tail ends of the embryo. They form the primitive foregut and hindgut. At either side of the neural tube the mesenchyme has become differentiated into eight prim-

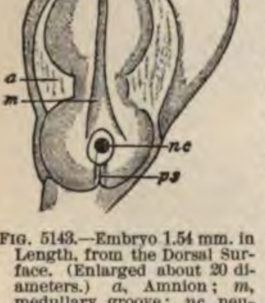

FIG. 5143.—Embryo 1.54 mm. in Length, from the Dorsal Surface. (Enlarged about 20 diameters.) *a*, Amnion; *m*, medullary groove; *nc*, neurenteric canal; *ps*, primitive streak; *y*, yolk sac. (von Spee.)

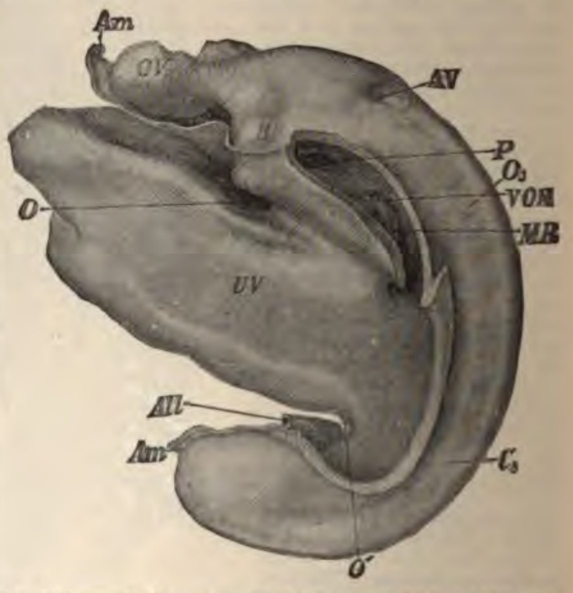

FIG. 5145.—Profile Reconstruction of the Embryo, 2.1 mm. Long. No. XII. × 37 times. *Am*, Amnion; *OV*, optic vesicle; *AV*, auditory vesicle; *UV*, umbilical vesicle; *H*, heart; *VOM*, omphalo-mesenteric vein; *MR*, septum transversum; O_3, third occipital myotome; C_8, eighth cervical myotome. (After Mall.)

itive segments or myotomes, from which later much of the muscular system becomes differentiated.

A slightly older embryo, of about the same length, described by Mall, consists of an ovum measuring 18 × 8 × 8 mm., and containing an embryo 2.1 mm. in length. The age is about two weeks (see Fig. 5145).

Many important changes have taken place. The embryo is connected to the chorion by a thinner stalk of mesenchyme containing the blood-vessels that carry on the circulation between the embryo and chorion, the latter being in close contact with the uterine wall, and thus affording opportunity for nourishment and oxygen to pass from the mother through the thin walls of the villi, to supply the rapidly growing embryo with the essentials for growth and life. The embryo itself has greatly increased in length, and is curved into a semicircular form. The medullary plate is converted into a tube and the groove into its canal. At the anterior end of this tube are enlargements marking the beginnings of the brain. The remainder of the tube forms the spinal cord. The yolk sac, which is covered by blood-vessels that communicate with those of the embryo, is more constricted and the fore- and hindguts are longer than in the preceding stage. From the foregut arises the pharynx with two gill pockets and a thyroid pocket. The neurenteric canal connects the hindgut with the central canal of the central nervous system. So while from the yolk sac are differentiating the two ends of the alimentary tract, the main portion is still embodied in the large sac. Near the origin of the foregut is a slight projection of the yolk sac for the beginning of the liver. In the anterior wall of the yolk sac, posteriorly to the mouth and beneath the pharynx, is the tubular heart. There are now fourteen pairs of mesenchymal segments or myotomes—three in the head, eight in the neck, and three in the thoracic region. The amnion at this period forms a small sac about the dorsal surface of the embryo.

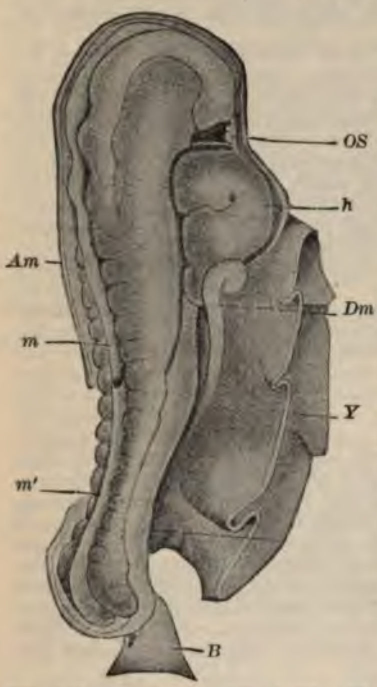

FIG. 5146.—Embryo 2.5 mm. Long. (Enlarged about 33 diameters.) *Am*, Amnion; *B*, belly stalk; *h*, heart; *m*, closed and *m'*, still open portions of the medullary groove; *Om*, omphalo-mesenteric vein; *OS*, oral fossa; *Y*, yolk sac. (Kollmann.)

In an embryo described by Kollmann (Fig. 5146), and measuring 2.5 mm. in length, the edges of the medullary folds have come in contact throughout their entire length except for a short distance anteriorly, and thirteen pairs of mesodermic somites or myotomes are visible. The constriction of the yolk sac is even more pronounced than in the preceding embryo, and the hind end of the body has become defined, the belly stalk no longer seeming to be a posterior continuation of the body, but arises from the ventral surface. The oral fossa is more marked.

The general shape of this embryo is quite different from that of the preceding one, the embryo being nearly straight; and it has probably been distorted, as has also the His embryo (Fig. 5147), as the normal curve of the medullary tube at this period is probably somewhat semicircular, as seen in Figs. 5145 and 5149. This so-called dorsal flexure, which is often pictured in text-books as a normal condition at this stage, I have been able to produce in pig embryos of a corresponding stage by rough handling while removing them from the uterus. Others from the same uterus, which were more carefully handled, do not show such a dorsal flexure, and we naturally conclude that similar treatment has produced a similar effect in the human embryo.

The His embryo Lg, 2.15 mm. long, contained in an ovum 15 × 12.5 mm., is the next important one to consider. Its age is about fourteen days. (Fig. 5147.) The forebrain has a marked ventral bend. Between the forebrain and the heart is now a well-marked invagination of the skin to form the mouth cavity. It is not as yet connected with the pharynx. Projecting from the forebrain are the optic vesicles, and farther back are invaginations of the ectoderm for the internal ear. Two gill clefts and three branchial arches are present, and branches of the aorta pass through the latter. The heart consists of a much bent tube.

The branchial arches and clefts are of great morphological importance, since they determine to a large extent the arrangement of the various organs of the head region. In the human embryo four clefts and five branchial arches appear on each side. The last arch is very indistinct.

We thus see that during the first two weeks, which constitute the ovum stage, there has developed from the simple one-celled ovum or egg an embryo with its membranes, the amnion and chorion, the latter having over its entire surface numerous long branching villi, and in the embryo are already present the beginnings of the central nervous system, the alimentary tract, the circulatory system, the muscular and skeletal systems, the latter being represented by the chorda dorsalis, which has differentiated from the dorsal wall of the entodermal sac and canal. The primitive urogenital system has also begun to appear. The yolk sac remains throughout this stage the dominant feature of the embryo.

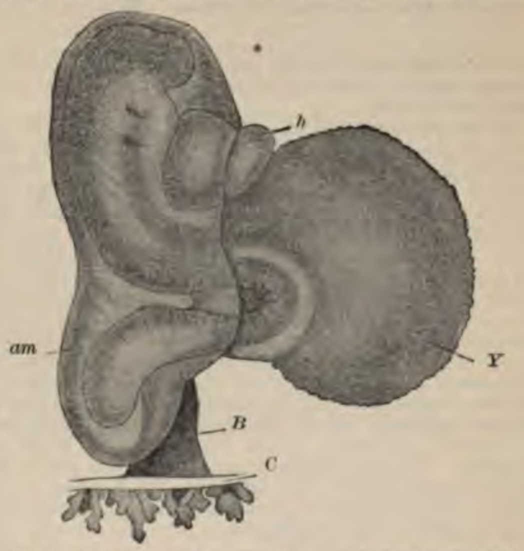

FIG. 5147.—Embryo Lg., 2.15 mm. Long. (Enlarged about 30 diameters.) *am*, Amnion; *B*, belly stalk; *C*, chorion; *h*, heart; *Y*, yolk sac. (His.)

The Embryonal Stage.—During the third week the embryo grows rapidly in size and attains a length of about 4 mm. The brain increases in size and shows the three primary divisions. The optic and otic vesicles become more prominent. Two more gill clefts and three more gill arches appear caudal to the ones already formed. The attached area of the yolk sac has diminished. The mouth cavity communicates with the pharynx. By the twenty-first day the limb buds appear (see Fig. 5148). Internally the heart is enlarged and takes the form of an S-shaped tube. From the aorta now arise five pairs of arteries which pass through the five pairs of gill arches, joining on the dorsal side of the pharynx into the common dorsal aorta.

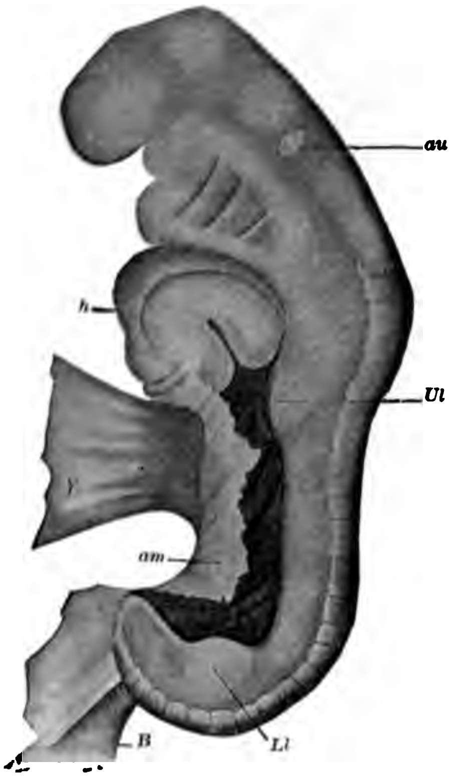

FIG. 5148.—Embryo Lr., 4.2 mm. Long. (Enlarged about 23 diameters.) *am*, Amnion; *au*, auditory capsule; *B*, belly stalk; *h*, heart; *Ll*, lower and *Ul*, upper limb; *Y*, yolk-sac. (His.)

By the narrowing of the attachment of the yolk sac more of the primitive gut has been folded off, so that now the foregut, midgut, and hindgut are to be distinguished. In the foregut can already be made out the pharynx with its diverticula, the œsophagus, and the stomach. Of the pharyngeal diverticula there are four pairs of gill pockets corresponding to the gill clefts on the external surface and separated from the gill clefts by a thin membrane. The diverticulum for the respiratory tract has begun to bud from the œsophagus. The first indication of the lungs and trachea is found in embryos of about 3.2 mm. in length in the form of a groove, the pulmonary groove, along most of the ventral surface of the œsophagus. During the embryonal stage this groove deepens especially toward the stomach, where it ends in a a rounded projection, which lengthens and gives off branches. These, by repeated branching, give rise to the various sized bronchi and the epithelial portion of the lungs. The pulmonary groove gradually becomes constricted off from the œsophagus to form the trachea. At the upper end, however, it remains open into the pharynx, in the region of the fourth branchial diverticulum, to form the glottis. The midgut gives rise to the small intestine and to a portion of the large intestine. From it have arisen diverticula which give rise to the liver and pancreas. The hindgut gives rise to the rest of the large intestine and to the rectum.

The primitive urogenital system has appeared as two longitudinal ridges projecting into the cœlom along its dorsal wall, one at either side of the median line in the posterior half of the embryo. This ridge contains the Wolffian duct, the pronephros with its two tubules and rudimentary glomeruli. The Wolffian duct, which is the first to appear, develops from the mesenchyme, and extends from the heart region to the cloaca. Soon after the non-functional pronephros is formed, the mesonephros begins to develop and its tubules join the Wolffian duct. The mesonephros is a much more important structure than the pronephros, and we shall consider it again later. The beginning of the Müllerian duct is also present at this stage.

During the fourth week growth is relatively more active than at any other time, except during the very early stages of the first week or ten days. The embryo about doubles in length, and attains a length by the end of this week of about 6 or 7 mm. During the first part of the week the embryo becomes very much flexed, so much so that the head and tail nearly touch. The brain vesicles are better developed, as are also the gill clefts and arches, the eyes, ears, and nasal pits. The heart, which is much enlarged, lies in the cervical region, near the mouth, and produces with the liver, which is now of considerable size, a large ventral bulge. The simple tubular heart with its single cavity is rapidly changing into a complicated four-chambered structure with imperfect partitions. By the end of the fourth week (see Fig. 5149) the anterior enlarged portion of the head has become bent at right angles to the main axis of the body. From the first gill arch a maxillary process is developing which will ultimately form a portion of the upper jaw. From the main portion of the arch will form the lower jaw. The limb buds have increased in size. The arm bud projects from the cervical region and the leg bud from the lumbar region. The yolk sac is very small and the amniotic sac is much enlarged. During the early part of the fourth week the intestinal tube, composed of its several characteristic segments, lies in the sagittal plane attached to the dorsal wall of the body cavity by the straight primitive mesentery. Toward the last of the week rapid growth takes place, the intestine lengthens, and becomes coiled and twisted.

The nerves have begun to grow from the medullary tube or central nervous system into the mesenchyme. Plexuses are forming, but the nerves are not attached to their end-organs. There are now thirty-eight primitive segments or myotomes which have been formed from the mesenchyme lateral to the spinal axis. Muscle fibres are beginning to differentiate from the cells of these segments. Their ventral ends have begun to grow into the primitive abdominal wall formed by the growing around of the amnion. Condensed mesenchyme marks portions of the vertebral column. In the arm bud the mesenchyme is beginning to differentiate to form the skeletal core of condensed mesenchyme. The Wolffian ridge has increased in size and the Müllerian duct is now formed and runs parallel with the Wolffian duct. A diverticulum from the lower end of the Wolffian duct near the cloaca indicates the beginning of the permanent kidney and its duct, the ureter. On the Wolffian ridges are also seen the first traces of the sexual glands, but they are indifferent in type, and not until the fifth week can sex be determined by microscopical examination.

By the middle of the fifth week the embryo is 9 mm. in length. The amniotic sac is now so much enlarged that it is everywhere in contact with the chorion. A true umbilical cord of some length has developed by the enclosure of the entire belly stalk and yolk stalk within a tubular prolongation of the embryonic ectoderm and somatic mesoderm of the embryo. The embryonic ectoderm at the end of the cord is continuous with the extra embryonic ectoderm of the amnion, and the somatic mesoderm with that of the amnion, which is in contact with that of the chorion. So, strictly speaking, the umbilical cord is a portion of the embryo, the amnion having been carried farther and farther from the umbilicus by extension of the embryonic ectoderm. The head is as large as the rest of the body, and bent at right angles to it. Its large size is due to the rapid growth of the brain. The three primary divisions of the brain are more marked and bent upon each other. From the forebrain the cerebral hemispheres have begun to grow. The spinal cord forms a thick-walled tube of nervous tissue. The various cranial and spinal nerves now extend some distance into the body and the motor nerves of the head and shoulder reach the premuscle masses. The rami communicantes are already present at this stage and connect with the sympathetic cord. The latter forms a continuous column of cells in front of the vertebræ, and has not as yet separated into ganglia. The sympathetic nerve cells have reached this position by migration from the ganglia of the dorsal roots.

At about this time the suprarenals commence their development and are found, at the beginning of the third month, occupying their characteristic position as a cap fitted over the head of the kidney. They rapidly acquire a very large size and at birth have their permanent volume. There is no developmental relation between the suprarenals and the kidney. The suprarenals are probably derived partially from the mesonephros and partially from the sympathetic nervous system, the latter giving rise to the medullary portion and the former to the cortical portion.

The gill clefts and arches are undergoing marked changes. From the first arch the upper and lower jaws are developing. From the first cleft the external auditory canal and ear drum are forming, and from the pharyngeal portion of the cleft the Eustachian tube and middle ear. The malleus and incus of the ear arise from the dorsal portion of the cartilage of the first gill arch, and from its ventral portion Meckel's cartilage. From the second arch are forming the stapes, styloid process, and the hyoid apparatus, to which later the tongue muscles become attached. The remaining arches and clefts are beginning to disappear by sinking into the depth of the neck, remaining connected with the surface, however, by a deep sinus, the so-called cervical sinus. Occasionally one may persist to adult life as a sinus or cyst. The arm and leg are enlarged and show two segments (see Fig. 5150). The skeletal system consists of a condensed mesenchymal tissue and precartilage. The premuscle masses of the head and arm are differentiating from the mesenchyme. Those of the trunk arising from the myotomes contain muscle fibres and are more advanced, while those of the limbs appear to develop *in situ* about the preskeletal mesenchyme, and show no fibrillation The heart still lies close to the mouth in the neck region. It is much changed in shape and is imperfectly four-chambered. The truncus arteriosus is undergoing division into two tubes by the formation of the aortic septum.

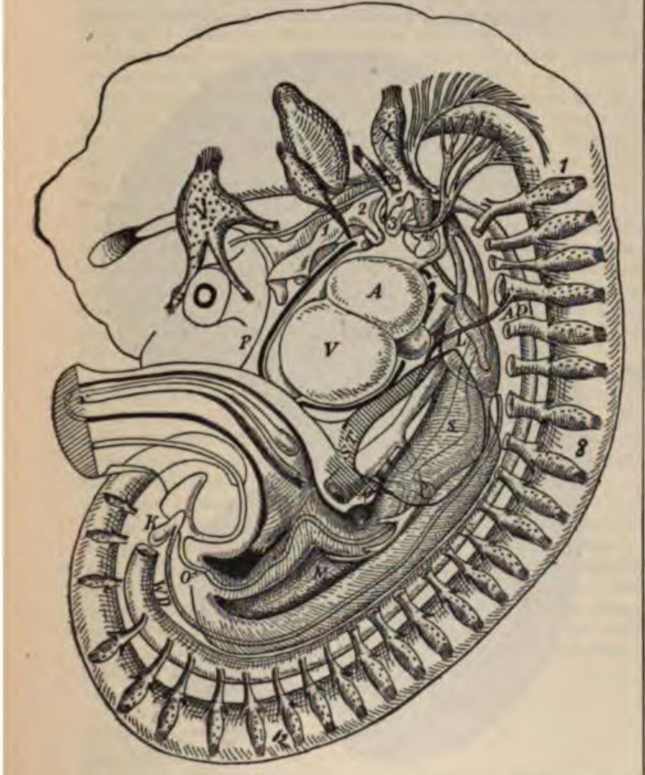

FIG. 5149.—Reconstruction of Embryo No. II., Johns Hopkins University Collection. (Enlarged 17 times.) *V* and *X*, Fifth and tenth cranial nerves; *1*, *2*, *3*, and *4*, cast of the branchial pockets; *1* and *8*, first and eighth cervical nerves, from the fourth the phrenic arises; *12*, twelfth dorsal nerve; *A*, auricle; *V*, ventricle; *L*, lung; *S*, stomach; *P*, pancreas; *W D*, Wolffian body; *K*, kidney; *M*, mesentery; *S T*, septum transversum; *O*, openings which communicate with the peritoneal cavity of the opposite side. The black line around the heart marks the pericardial cavity. (After Mall.)

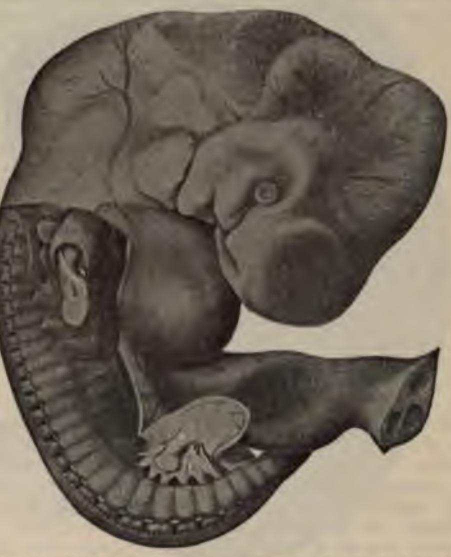

FIG. 5150.—Lateral View of a Human Embryo 9 mm. in Length and About Four and One-half Weeks Old. No. CLXIII. Johns Hopkins University Collection. (Enlarged about 8 diameters.) The areas from which the skin has been removed are drawn from reconstructions, the remaining portions from excellent photographs. The myotomes are growing into the body wall. Portions of the premuscle masses of the arm are seen and also the preskeletal tissue of the arm and leg with the beginnings of the lumbar sacral plexuses. (After Bardeen and Lewis.)

The modification of the primary arterial system is progressing rapidly. The main portions of the first two arches have disappeared, giving rise with the third arch to the common carotids and their branches. From the last arch the pulmonary arteries are developing, and from the fourth, which seems to be a combination of the fourth and fifth, develop the large aortic arch on the left side and innominate and subclavian on the right side. The latter, however, still retains its connection with the dorsal aorta, giving a condition found in reptiles. The important connection of the last arch on the left side with the aorta remains of large size, and that portion of it between the pulmonary artery and the aorta forms the ductus arteriosus, a very important fœtal structure, as it enables the venous blood from the right side of the heart to pass into the aorta without going through the lungs. The growth of the liver has also been an important factor in bringing about modifications in the venous system. With the diminution of the umbilical vesicle the extra embryonic portion of the omphalo-mesenterics disappears, but the embryonic portions of the two veins form the portal

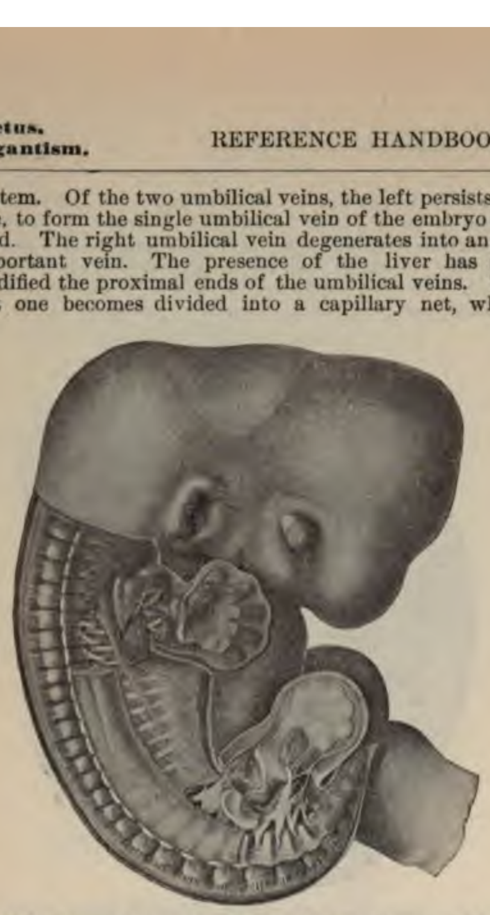

FIG. 5151.—Lateral View of a Human Embryo 11 mm. in Length and About Five Weeks Old. No. CIX., Johns Hopkins University Collection. (Enlarged about 7 diameters.) The dissected area was drawn from a reconstruction. (After Bardeen and Lewis.)

system. Of the two umbilical veins, the left persists entire, to form the single umbilical vein of the embryo and cord. The right umbilical vein degenerates into an unimportant vein. The presence of the liver has also modified the proximal ends of the umbilical veins. The left one becomes divided into a capillary net, which again collects into a short vein that opens into the sinus venosus. The development of the ductus venosus soon forms a channel for most of the blood carried by the umbilical vein. The proximal portion of the inferior vena cava is developed as a new structure. The distal end of this unites with the right inferior cardinal in the region where the renal arteries arise; and the caudal continuation of the cardinal from this point of union becomes the inferior portion of the vena cava. The remaining portions of the two cardinals form the azygos veins. A cross anastomosis develops from the left jugular to the right jugular, and from the common stem thus formed develops the superior vena cava. The proximal portion of the ductus Cuvieri on the left side then loses its connection with the jugular and becomes the coronary sinus of the heart.

By the time the embryo is five weeks old it has attained a length of 11 mm. (see Fig. 5151). The head is still very large and bent at right angles to the main axis of the body. The maxillary and nasal processes, which fuse at a later stage to form the upper jaw, are now more marked and approaching each other. The external nares are nearing the middle line. The external ear is represented by several small protuberances about the first cleft. The general body musculature is well advanced and has its nerve supply. The ribs and the muscles of the thorax and abdomen have grown some distance into the thin membrane, membrana reuniens, which in early stages constitutes the ventral body wall. The limbs are much enlarged and contain a skeletal core of cartilage surrounded by the developing muscles. The arm keeps about two weeks in advance of the leg in its internal differentiation. The vertebral column and ribs are formed partially in cartilage. The fourth pair of the aortic arches still persists entire and the others are modified in various ways to form the larger arteries in this region. The liver has been increasing rapidly in size, and in this embryo as in the preceding stage forms with the heart most of the large projecting abdomen and thorax. The allantois forms a long narrow tube extending from the hindgut into the umbilical cord as far as the chorion. At a later stage the umbilical portion becomes obliterated, while the portion near the hindgut enlarges into the bladder.

During the fifth week the œsophagus elongates and the stomach acquires its characteristic form, as well as an obliquely transverse position, its former left side becoming directed anteriorly and upward, and its former right side looking backward and downward. This explains the distribution of the left vagus nerve to the front of the stomach and the right to the back; for, before this twisting of the stomach began, these nerves had already reached the stomach. The connection of the yolk stalk or vitelline duct with the intestinal canal rapidly becomes less marked, and by the end of this week only a small duct attaches the yolk sac to the intestine.

During the last part of the embryonal stage and the first part of the fœtal stage there are very important shiftings or migrations of various organs in the body. That of the heart and diaphragm from the cervical region into the thoracic region is of especial interest, as other structures are dragged along with them. The large blood-vessels are pulled downward, and such nerves as the recurrent laryngeals indicate this process. Originally they passed directly from the vagus to the larynx just posterior to the fifth aortic arch, and by the migration of the heart and large blood-vessels they are brought into the position seen in the adult. The diaphragm in its descent obtains muscle tissue and its nerve in the cervical region, and both are then carried down to the lower part of the thorax. The limbs also exhibit a migration, the arm from the cervical to the thoracic region giving the caudal inclination to the brachial plexus, which originally went straight out into the arm without this caudal inclination. The leg likewise migrates. Many individual muscles also take part in this shifting and migrating, such as the trapezius from the upper cervical region and the

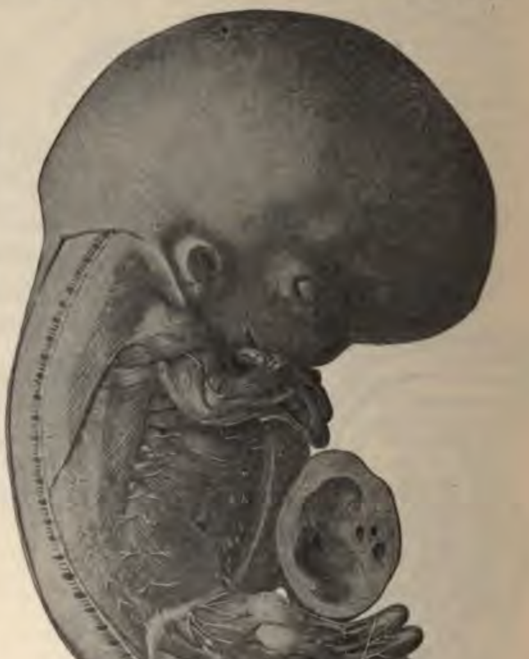

FIG. 5152.—Drawing from a Reconstruction of a Human Embryo 20 mm. in Length and About Seven Weeks Old. No. XXII., Johns Hopkins University Collection. (Enlarged about 5 diameters.) The muscular systems of the limbs and body wall are seen to be well developed. (After Bardeen and Lewis.)

;issimus dorsi from the lower cervical. The path of the rve from its exit at the intervertebral foramen to its int of entrance into the muscle indicates the path the grating muscle has taken, while the branching within : muscle probably indicates the direction in which the iscle has increased in size.

During the embryonal stage the yolk sac has diminished to an organ of relatively small size and importance, ile the central nervous system, with its greatly enged anterior end, the brain, giving to the head its at prominence, becomes the predominating feature of embyo. The head throughout most of this stage is ut equal in bulk to the rest of the body of the em- o.

etal Stage.—In an embyro seven weeks old and 20 ı. long the early fœtal features are fairly well marked. : head is nearly erect. The fusion of the maxillary nasal processes is proceeding rapidly to form the er jaw, and the nasal pits have approached nearer to median line. Failure of fusion between these proc- s gives rise to the various forms of cleft palate and lip. The arms and legs are much elongated, and v the three segments seen in adults. Fingers and are also to be distinguished. Practically every mus- f the body can now be recognized, and has also its e supply (see Fig. 5152). Most of the skeletal ele- ts are present in cartilage. Portions of the skull, ever, are never so represented, but ossification takes e directly from the condensed mesenchyme. The have extended nearly to the mid-ventral line. The icic and abdominal muscles have likewise pushed ier out into the ventral wall of the body.

the end of the second month the permanent kidney irly well formed and the Wolffian body, which so ı the life of the embryo has performed the function excretory organ, begins to lose its importance. All the middle portion, which later forms the sexual l, atrophies. Its duct in the male forms the vas ens, in the female degenerates, while in the female lüllerian ducts form the Fallopian tubes and uterus, n the male degenerate. Thus by the end of the sec- nonth most of the organs which are found in the are formed. The main processes which now take until birth are the growth and shifting about of organs.

: *third month* establishes the human form, although ad still unduly predominates. The limbs have ac- l their definite shape, and the imperfect nails are ıt on both fingers and toes. The external organs of ation become definitely differentiated, although nake their appearance several weeks earlier.

he female the genital tubercle remains much less ped to form the clitoris. The genital furrow re- open to form the vestibule and the genital swell- ıe labia majora. The prepuce and labia minora ping from the genital folds, lie at either side of the l sinus. The genital swellings in the male when evelop into the scrotum have layers identical with of the abdominal wall, as seen in the following :

minal Walls.	*Scrotum.*
ment.	Integument.
icial fascia.	Dartos.
al oblique muscle.	Intercolumnar fascia.
ıl oblique muscle.	Cremasteric.
ersalis muscle.	Infundibuliform fascia.
eum.	Tunica vaginalis.

tunica vaginalis lines the sac, communicating vith the peritoneal cavity; and into this sac later icle descends. The anterior end of the ureter now the neighborhood of the suprarenal where it ends kidney, which consists of about eighteen lobes, each group of tubules connected with the ureter. bulation persists until after birth. The supra- ow fit caplike over the anterior end of the kidney. end of the month the fœtus weighs about 120 gm. (3¼ ounces), and measures about 5 cm. (2 inches) in length.

During the *fourth month* hairs devoid of pigment appear on the scalp and other parts of the body, which is now covered with firmer skin of a rosy hue. The eyelids, nostrils, and lips are closed. The anus opens, and the coils of intestine, which before extended into the umbilical cord, now lie entirely within the abdominal cavity. The point of emergence of the umbilical cord lies low down close to the pubes. The head forms about one-fourth of the entire body. The bones of the skull while ossifying are still widely separated. The sexual distinctions of the external genital organs are well defined. By the end of this month the fœtus weighs about 230 gm. (7¼ ounces), and measures about 10 cm. (4¼ inches) in length.

During the *fifth month* the lower extremities become longer than the arms, nails are well formed, and hairs are more plentiful, but devoid of color. The fœtal movements are distinctly felt by the mother. The sudoriparous glands arise during this month as solid cylindrical outgrowths from the primary ridges of the epidermis into the dermis. Later they become coiled and a lumen appears. The heart and liver share with the head in the undue preponderance which these parts present. At the end of this month the fœtus measures 20 cm. (8 inches) in length, and weighs about 500 gm. (1 pound).

During the *sixth month* the surface presents many wrinkles and is of a dirty reddish hue; the sebaceous coating, the vernix caseosa, begins to appear. This whitish substance is composed of shed surface epithelium, mingled with the secretions of the sebaceous glands; its primary function seems to be the protection of the integument from maceration by the amniotic fluid. The eyebrows and eyelashes begin to grow. The length of the fœtus by the end of this month is about 30 cm. (12 inches), and its weight about 1,000 gm. (2 pounds).

The Seventh Month.—The formation of fat causes an appearance of greater plumpness, although the surface is still somewhat wrinkled. The hairs are longer, about 5 mm. in length. The eyelids are now permanently open. The liver is still relatively large; the testicles have descended as far as, or even into, the inguinal canals. Children born at the end of this month may live. The fœtus measures at the end of this period about 37 cm. long (15 inches), and weighs about 1,500 gm. (3 pounds).

The Eighth Month.—This and the ninth month complete the fœtal period. The chief changes are great increase in weight, as by the end of the eighth month the fœtus weighs from 2 to 2.5 kgm. (4 to 5 pounds) and measures about 42 cm. in length. The scalp is well supplied with hair, and the finger nails almost reach the finger tips. The lanugo or embryonal down begins to disappear. The subcutaneous fat has increased considerably, giving a more rounded form to the body.

The Ninth Month.—During this month there is a relatively large increase in weight, from 2 to 2.5 kgm. to about 3 or 3.5 kgm. (6 to 7 pounds), while the increase in length is only from about 42 to 50 cm. (20 inches). The skin is less highly colored and the lanugo has almost entirely disappeared. The testicles have descended into the scrotum; in the female the labia majora are in contact. Centres of ossification usually appear in the epiphysis at the lower end of the femur, and often in the upper epiphyses of the tibia and humerus.

Warren Harmon Lewis.

GIGANTISM, GENERAL.—The word giant is derived from the Middle English "geant," the equivalent of the French "géant," which may be traced back to the Greek *γίγας*.

Very early in the world's history we meet with references to huge beings of supernatural strength. Even before the flood, in the story of Noah, we are informed that "there were giants in the land in those days," and there are stray allusions to giants, Emmim and Anakim, in the accounts of the early Jewish conquests, in the sight of whom the people were "as grasshoppers," to use the characteristic Eastern hyperbole. Later, we have the celebrated battle between David and Goliath of Gath, one of the few remaining descendants of these Anakim, whose height was six cubits and a span. The Greeks, also, had their giants in the man-eating Cyclopes and Lestrygones. The Titans, too, forty-five in number, whose children were the Gigantes, were of enormous size. They did not fear to encounter the gods, and were said to have heaped up mountains, to have "piled Ossa on Pelion," in order to scale the heavens. All nations, alike in their love of the marvellous and their sympathy with the weaker side, have their stories of unequal battles, recalling the struggle between the pygmies and the giants, waged between brave men and monsters of immense size and strength, in which the lesser power comes off the conqueror. An instance that will be familiar to all is the popular nursery tale of "Jack the Giant-killer," which used to delight us so much in our youth. As is usually the case, human credulity and the innate tendency to exaggeration have magnified many of these tales beyond the bounds of credibility. While it must be admitted that in former times there have been individuals and even races that far exceeded in strength and stature the ordinary run of mankind, the application of the rigid canons of modern scientific inquiry has resulted in the dethronement of the supernatural element and the reduction of the subject, though marvellous enough still, to more manageable proportions. Before passing on to discuss the nature of this curious anomaly of development that we call gigantism, we may with advantage pause for a moment to determine what constitutes giant growth.

This is not so easy as it seems. If any one asks himself the question, "Where does giant growth begin?" he will at once realize that his ideas are somewhat hazy and his language conventional. In popular parlance a giant may be said to be any individual who exceeds in a notable degree the average height of human beings. A person of six feet six or upward would probably be called gigantic. This is, of course, an exceedingly loose and by no means scientific definition. It fixes no limits, it takes no account of weight and strength; in short, it lacks precision. Larcher[1] defines a giant to be "A being who, free in other respects from all defect in the essential characteristics of the organization, excels notably in height other beings of the same race who have reached adult age." In such a case the structural harmony and the relationships between the different parts are manifestly normal, the sole deviation being the striking increase in height. It is scarcely necessary to point out that this definition portrays for us the ideal or perfect giant, a being rather more imaginary than real. No doubt there have been individuals of great size and strength, handsome, well proportioned, and well balanced in all their faculties, but these are the *raræ* or rather the *rarissimæ aves*. As a matter of fact, the immense majority of giants present the unmistakable stigmata of defect or degeneration. The definition further ignores the fact that gigantism is a process, an anomalous one it is true, but still a process of growth which may and does manifest itself in embryonic life and childhood, as well as in the adult stage. Pierre Marie[2] recognizes two forms of gigantism: (1) *True gigantism*, consisting in a simple exaggeration of the normal process of growth; and (2) *symptomatic gigantism*, a manifestation of pre-existing disease. Meige[3] would restrict the term gigantism to Marie's second class on the ground that the members of the first group are in all respects normal persons, differing in no way, save in height, from other individuals of the same species. This, while no doubt contributing to precision of language and lessening the possibility of confusion in description, is in my opinion too extreme a position to take, for who will maintain that an exaggeration of a normal process of growth is not a pathological manifestation? We ought not, therefore, rashly to conclude that true gigantism and symptomatic gigantism are necessarily or essentially different processes, or that the former should be left out of our consideration of the general subject of gigantism. We shall be helped considerably toward a proper conception of what constitutes giant growth if we consider briefly what may be called the "law of deviation" enunciated by Thoma.

Thoma[4] states, on the basis of an extended series of observations, that in adults the normal length of the body averages approximately 169 cm. in the male and 163 cm. in the female: the normal average body weight is 60 kgm. and 56 kgm. respectively. Considerable variations on one or other side of this norm occur. In one-half the total number of individuals the amount of deviation is anywhere from 0.0 to 3.8 cm. for height, and from 0.0 to 5 kgm. for weight. In accordance with observations he has made, Thoma finds that the fifth multiple of the figures representing the amount of normal deviation, namely, 19 cm. and 25 kgm., is exceeded only once in a thousand individuals. According to this an adult male would be regarded as a giant if his height exceeded 169 plus 19 or 188 cm., or if his weight were more than 60 plus 25 or 85 kgm. The normal limits, however, for the upper well-nourished classes are somewhat higher than the figures given, namely, 175 cm. and 66 kgm., so that the lower limit for giant growth would be more correctly placed at 175 plus 19 or 194 cm., and 66 plus 25, or 91 kgm. (6 feet 4⅜ inches, and 200 pounds 5½ ounces). In the case of new-born infants the normal average for length is 50 cm. and for weight 3.2 kgm. The amount of deviation is approximately 1.4 cm. and 0.28 kgm. respectively. Applying the same rule we may assume giant growth in children if they exceed 57 cm. in length and 4.6 kgm. in weight. For Thoma, then, a giant is literally a man in a thousand. We cannot, however, assume that because an individual exceeds these dimensions he is necessarily a giant. It should be noted that height and weight are not necessarily closely correlated. In true gigantism no doubt they would be, but in many cases we find that those gigantic in stature are not heavier than many normal persons. This is often to be explained on the score of some wasting disease which is present, or that the individuals in question have died or been observed before the consolidation of the body had been properly attained. Further, an excess in weight above the limit of 91 kgm. cannot in itself constitute gigantism, for this weight is frequently attained by those who would be regarded as normal individuals, and has also been attained in cases of diffuse lipomatosis, elephantiasis, and when large tumors are present. Gigantism is quite different from this. Properly understood, it implies not a mere increase in the bulk of any tissue or group of tissues, but rather an abnormal increase in the size of the body as a whole, due to some peculiar and inherent nutritive disturbance. The term *macrogenesy* would perhaps most correctly designate the condition.

Gigantism manifests itself in an excessive growth of the bones, more especially in the direction of length, but also to some extent in thickness. The long bones are most noticeably involved, but all the bones of the body may be to some degree affected. With this there is a corresponding increase in size of the nerves, vessels, and soft tissues generally. The most striking and constant feature in giants, however, is their great height. The deviation in weight is less apparent, is usually less and never more than the increase in height would warrant.

From a pathological standpoint gigantism belongs to the group of tissue hypertrophies, of which there are many less extreme manifestations than the complete giant. Local hypertrophies of undoubtedly developmental origin are not infrequently met with, particularly in the head and extremities. In the case of the head the bones of the cranium and face are usually involved, giving rise to an extensive and remarkable deformity (leontiasis ossea of Virchow), the exact nature of which is somewhat obscure but appears to be essentially a diffuse hyperostosis. The form found in childhood is especially common in the upper limbs, and may be unilateral or bilateral. Apart from these instances of local gigantism, which are characterized mainly by an abnormal increase in the bulk of the affected part, there are other condi-

s, regarded by some as forms of gigantism, in which
excess is numerical, as, for example, polydactylism,
ssory ribs and vertebræ, and supernumerary organs.
igantism, or macrogenesy, is comparatively rare as a
genital anomaly. Fuchs[5] in the extensive material
he Lying-in Hospital at Kiel found the average
ght of the new-born child at full term to be from 8 to
gm., figures which agree accurately with those given
homa. This limit was not often passed, and a body
ht of 5 kgm. (11 pounds) was of the greatest rarity.

er[7] observed two infants weighing 5.2 and 6 kgm.
ctively. Baudelocque[8] in many years saw only one
t that reached 6.875 kgm. Fuchs (*loc. cit.*) has
ibed in detail two infants that weighed 6.1 and 7.55
and measured 60 and 65 cm. respectively. The
extensive statistics are those of von Winckel,[9] who
000 births found no child reaching 6 kgm.; in 17,000
at Munich only 5 were found weighing from 5 to
gm. These dimensions, striking as they are, have
onsiderably surpassed by some found in English and
ican literature. Eddowes[10] mentions the birth of a
weighing twenty-two pounds two ounces. The
r was thirty-three years of age, and had previously
two children of large size. Chubb[11] met with one

ilos. Trans. of the Royal Soc. of London). The
nt history of unusually large children is unfor-
not often to be traced, but there is some slight evidence to show that they may develop into gigantic adults. Bonardi[16] reports an interesting case which throws some light upon this point. A boy at the age of fifteen had the size and development of an adult male. At twenty-two he began to suffer from pains in the head with nausea, and soon after the hands, feet, maxillæ, and tongue began to increase in size. At the age of twenty-nine he measured 194 cm., and presented all the signs of acromegaly. In other instances, too, the abnormal increase in size has been known to begin quite early. Gilbert of the Hôpital Broussais (quoted by Meige, *loc. cit.*, p. 449) met with an individual who began to grow rapidly after an attack of some acute fever in his earliest infancy and eventually attained the height of 196 cm. The American giant Wilkins began to grow rapidly at the age of four, and reached his full height (245 cm.) at eighteen. As a rule, however, the excessive growth does not become in evidence until some time between the tenth and twentieth years, usually with the onset of puberty.

The student of ancient lore will be interested and amused to see how superstition and the love of the marvellous have combined to render many of the accounts of giants that have come down to us thoroughly unreliable. Judging from these stories, the height to which the human race may attain has varied between wide limits. Pliny, like Augustine, believed that the stature of mankind had deteriorated, but this is not substantiated by the examination of such ancient remains as we possess. The rabbinical legends teem with incredible accounts of the height of the various Biblical characters. Adam's height was calculated to be one hundred and twenty-three feet and Eve's one hundred and eighteen. According to the Biblical account the bedstead of Og, King of Bashan, was nine cubits long. Pliny mentions the giant Gabbaras, between nine and ten feet high, who was brought from Arabia by the Emperor Claudius, and states further that the remains of Posio and Secundilla, found in the Sallustian Gardens in the time of Augustus Cæsar, measured each ten feet three. Josephus refers to a Jew nearly eleven feet high, who was sent as a hostage to Rome by the King of Persia. Some remarkable stories are told of the Emperor Maximin (C. Julius Verus Maximinus) who was born in 173 in one of the frontier villages of Thrace. A shepherd in his youth, he soon became noted for his extraordinary height and strength. He took part in the games given by Septimus Severus to celebrate the occasion of the birth of his son, and overcame sixteen of the most powerful wrestlers without taking breath. The Emperor attached him to his own person and he was made a centurion by Caracalla. Capitolinus says that he was a finger's breadth over eight feet in height. His thumb was so large that he could use his wife's bracelet for a ring. He stopped a wagon with one hand, broke the jaw of a horse with a blow of his fist, and could break its leg with a kick. He is credited with eating forty pounds of meat in a day and used to drink as much as a Capitoline amphora (about twenty-six litres). He became tribune under Alexander Severus, and, conspiring against him later, was elected emperor. He reigned for three years, execrated for his cruelty, and was finally assassinated by the soldiers in 238.

Coming to more recent times, we have some equally extraordinary tales brought back by travellers. Magellan is said by some to have given the name Patagonia to the country he discovered because its inhabitants measured five cubits. Lemaire, in describing his voyage in 1615 to the Straits of Magellan, states that at Port Desire he found several graves covered with stones in which were skeletons of men measuring from ten to eleven feet. More recent travellers have, however, found the Patagonians to be not excessively large; in fact many of them are rather diminutive. The naturalist Turner believed that he saw on the River Plata near the coast of Brazil savages twelve feet high. Accounts more marvellous still are given of giants from nineteen to thirty-six feet high, who have existed at various times in Europe. These are based on the discovery of bones of prodigious size, which were erroneously regarded as human. In those days nothing was known about comparative anatomy, and the remains in question were no doubt those of some of the lower animals. Sir Hans Sloane, in an elaborate and learned disquisition on the subject, came to the conclusion that the bones referred to were parts of whales, mastodons, elephants, or other enormous beasts, although he thought that some of the stories could not be entirely discredited. It is a fact, however, that in more recent times, when such matters are much more narrowly scrutinized, no such instances of excessive height can be substantiated. Buffon, the great naturalist, usually a reliable authority, had no doubt that human beings had existed who were from ten to fifteen feet high. It is not until we come to the eighteenth century that we get reliable data as to the height of giants. According to Dana [16] not more than a hundred giants have been exhibited in public since 1700, and of this number only about twenty were said to have been over eight feet. Topinard measured the tallest man in the Austrian army, and found him to be eight feet four and a half inches. Winckelmeyer was eight feet six inches. Marianne Wehde, a more recent German giantess, was eight feet four and a half inches when sixteen and a half years old. In view of these observations we must seriously question whether any human being has ever exceeded nine feet in height. Quite a number of giants have been recorded who measured between seven and eight feet, but above this limit the cases are extremely few. The history of these is often extremely interesting. Queen Elizabeth's porter, whose portrait, painted by Zucchero, is now in Hampton Court Palace, was seven feet six inches high. Walter Parson, the porter of James I., was as big. William Evans, the porter of Charles I., was about eight feet high. Cromwell's porter, Daniel, who died a lunatic, attained the height of seven feet six. In the reign of George I., an Englishman, seventeen years old and eight feet tall, was exhibited at the Bartholomew Fair at Smithfield. "Big Sam," the porter at Carleton Place when George IV. was Prince of Wales, was eight feet in height. In a Dutch village in 1712 there died a fisherman called Gerrit Bastiaansen, who measured eight feet and weighed five hundred pounds. As a contrast to this we may cite a giant who was exhibited at St. Petersburg in 1829, who measured eight feet eight, but withal was thin and emaciated.

One of the most celebrated giants was Cornelius McGrath, whose skeleton is now in the museum of Trinity College, Dublin. He was born in 1736 in the county of Tipperary. His parents and the other members of the family were of ordinary size. After the age of fifteen he began to suffer from violent pains in the limbs and began to grow rapidly. At the age of sixteen he was six feet nine. In 1753, six months later, when he first exhibited in public he measured seven feet three inches in his stocking feet. It is said that he was ungraceful in appearance, of low intelligence, and spoke in a childish manner. He died at the early age of twenty-four. His skeleton measures seven feet eight inches.

John Middleton, called the "Child of Hale," was born in 1752 at Hale in Lancashire. His portrait is preserved in Brazenose College. He is said to have measured nine feet three inches.

O'Brien or Byrne, the "Irish Giant," is celebrated not only for his great height, but for his connection with the distinguished anatomist John Hunter. Hunter was particularly anxious to secure his body and made the most extraordinary exertions to obtain it. O'Brien was aware of this desire on the part of the anatomist and was correspondingly averse to being "set up" as a specimen. Shortly before his death, which occurred at the age of twenty-two, O'Brien bribed some of his friends to take his body, and after weighting it with lead to sink it in the sea. The undertaker, however, who had been previously interviewed by Hunter, managed to have the coffin locked up in a barn while the escort was refreshing at an inn. Thereupon some men, stationed there for the purpose, substituted an equal weight of paving stones for the body which was forwarded that night to Hunter. He took it in his carriage to Earl's Court, where it was immediately prepared. It is estimated that it cost nearly five hundred pounds to secure the body. O'Brien is said at the time of his death to have been eight feet four inches high. His skeleton, however, measures only seven feet seven. It is now, together with the kettle in which the body was boiled, in the museum of the Royal College of Surgeons in London.

The successor of O'Brien, Patrick Cotter, who for a time exhibited under his name, was born in 1761. At his death, which occurred at the age of forty-five, he is variously estimated to have been from eight feet one to eight feet seven in height. At one time he was examined by Dr. William Blair, who found him to measure about seven feet ten. He was badly proportioned, and looked like a weakly or even imbecile person. His forehead was low, his pulse feeble, his voice weak, and he suggested in appearance a sickly child that had grown too fast.

Robert Hale, the "Norfolk Giant," who died at Yarmouth in 1843 at the age of forty-three, was seven feet and a half high and weighed four hundred and fifty-two pounds.

Among the better known of the exhibited giants were Captain Bates, of Kentucky, and his wife, Anna Swann, of Nova Scotia. Captain Bates enlisted in the Southern army at the beginning of the American Civil War, being readily accepted on account of his size, although he was only sixteen years of age. By the end of the war he had attained the height of seven feet two and a half inches. He gradually increased in weight also until he turned the scale at four hundred and fifty pounds. While in England in 1871 he married at St. Martin's-in-the-Fields Miss Anna Swann, who measured seven feet five and a half inches. On neither side were the parents of more than ordinary stature.

Chang, a celebrated Chinese giant, died at Bournemouth in 1896, at the supposed age of fifty-one. He was upward of eight feet high.

At the Alhambra in London in 1882 was exhibited the "Queen of the Amazons," who was eighteen years old, and measured eight feet and half an inch.

We owe much of our present knowledge of the processes of growth and development to the epoch-making work of Winslow, Haller, Meckel, and the Saint-Hilaires, father and son. Although of late the interest of scientific men has been somewhat revived in the subject we cannot as yet be said to have made much advance, except that we are beginning to apprehend more fully the nature of the problems involved. We are now realizing the fact that growth and development are a very complicated matter. We see, for instance, that we must draw a distinction between mere growth, or what may be called vegetative force, function, and reproductive power. These three factors are more or less correlated, but the correlation often varies both in kind and in degree. Certain cells are specialized for growth, others for function, others for proliferation. All cells may at some time in their life history be specialized in one or other of these directions according to the demands made upon them, but they cannot be specialized in all three directions to the same extent at the same time. Thus a cell that is about to divide ceases to grow and enters into a resting stage before mitosis occurs. And other illustrations might be given. Moreover, what is true of the cell is true of the community of cells known as the individual. Up to a certain period of life the forces of the body are concentrated toward the main object of growth. Later, function becomes more in evidence. Last of all the power of reproduction becomes established and perfected. In gigantism disturbance of growth in the direction of increased stature and weight is the predominant feature, but, as we shall see, this does not occur as a rule without exacting a corresponding penalty in the degradation of the general bodily functions and the power of reproduction. The causes which lead to this result may be inherent in the germ cells so that they make their influence felt quickly in the construction of the organism,

hey may become operative subsequently to fertilization
l segmentation of the ovum, either during intra-uter-
life or after birth. These influences may, further, be
rted upon the body as a whole or on some part of it.
re is therefore a family relationship between gigant-
, dwarfism, and the various malformations and mon-
sities. In both dwarfism and gigantism, which are
, as might at first sight be supposed, perfect opposites
of the other, there is not merely an inhibition or an
ggeration of the normal processes of growth, but in
vast majority of cases something more, namely, a
version of growth. In the normal infant at birth, the
l and trunk, but particularly the head, are relatively
e. As the time of puberty approaches the picture
ges. Growth is rapid and irregular. The limbs are
disproportionately large, the hands and feet being
cially prominent. To use a common expression the
l has become the hobbledehoy. Only in the later
d of puberty does the trunk enlarge, the figure con-
ate, until the perfect proportions of the adult are
ned. There is a striking parallel between the hob-
hoy stage and what we find in gigantism. In
s the exaggeration of growth is also disproportion-
nd irregular. The head is often small, or at least
t the same size as the head of a normal youth or
of the same age; the increase in height is mainly
the excessive growth of the lower extremities as
ared with the rest of the body. Here, however, the
lel ceases. Giants are often weakly rather than
g; the sexual organs are apt to be badly developed,
he sexual proclivities are sluggish or delayed.
are liable to contract disease and show signs of
ture senility; in fact they rarely reach middle life.
fs, on the contrary, are long-lived. They frequent-
e the relatively large head of the infant, with evi-
s of delayed ossification of the cartilages, and
l inadequacy, facts which have caused many to
dwarf growth as really infantilism. Unlike the
they frequently possess average or more than
e mental powers. It is clear that in both gigant-
d dwarfism the disturbance, whatever it is, mani-
self mainly in the rate and extent of the growth,
ill to a noteworthy degree in disordered function.
is not merely the process of ossification that is at
ut the body as a whole—bones, soft parts, and in-
rgans—is involved. Nevertheless the disturbance
fication appears to be the controlling force, for it
tedly dominates the picture.
ally, the growth of bone depends on the activity
ain specialized cells—the osteoblasts—which are
situated in the deeper layers of the periosteum, at
remities of the bones, and along the interosseous
. Growth in thickness takes place from subperi-
steoplasia; growth in length is due to the influ-
the osteoblasts in the spongy ends of the bones
he epiphyseal cartilages. Inhibition or exaggera-
stature is due in the main to dystrophic changes
extremities of the long bones, although subperi-
steogenesis is also to some extent interfered
The results depend not only on the inherent vege-
rces at work in the cells, but on the condition of
hyseal discs. So long as the discs are movable,
in length of the bone is possible. This is inter-
borne out by recent investigations with the
certain forms of anomalous growth. Joachims-
und in some lilliputians that he examined that
formation was delayed, and the condition of the
l of the bone generally was strictly comparable
und in the child, although the subjects were in
hborhood of thirty years of age. Hofmeister[18]
etinism found that the epiphyseal discs persisted
g time, and that the epiphyseal ends of the bones
wly. In chondrodystrophia fœtalis an ingrowth
teum has in some cases been observed between
and the end of the bone. The significance of
t quite clear. In acromegaly, on the contrary,
e increase of size of the bones, still at the distal
n breadth and thickness, rather than in length,

there is complete union or synostosis of the epiphyses. With regard to giants we unfortunately have no information on this point, but I think we may fairly infer that, while growth is in excess, epiphyseal synostosis is delayed. The importance of the condition of the epiphyseal discs in modifying the extent and the direction of the growth is also prettily illustrated by the observation of Lorain, who found in some cases of dwarfism premature ossification and union of the epiphyses.

In our discussion of growth and its anomalies so far we have contented ourselves mainly with freeing the subject from entanglements, and so to speak preparing the ground for action. When we come to consider the more remote factors concerned in the question of growth we find ourselves in a much more difficult position. As we do not know what life is we can apprehend its methods and its manifestations only in an imperfect way. Many of our ideas, therefore, have to be based upon inference rather than direct proof.

The part played by heredity in gigantism, as in other anomalies of development, is of considerable interest and importance. This factor might be expected to be more prominent in cases of congenital gigantism, and as a matter of fact it is so, but its influence cannot be overlooked in the other forms. It is a matter of common observation that parents transmit their tendencies and peculiarities to their offspring, and moreover these peculiarities may be traced through several generations; in fact they may become familial or racial characteristics. This law manifests itself in many ways, in the size and configuration of the body, in the color of the skin, the mentality, habits, the susceptibility to disease, and in many minor traits. The peculiarities derived from the paternal and maternal sides may be of such a nature as to neutralize one another, or again they may unite their forces to produce an exaggerated effect, an effect so pronounced as to be marked at once as an anomaly. With regard more particularly to gigantism, we do not meet with the anomaly as a racial characteristic at the present day. At most we can say that some races tend to be tall and large, while others are small or even dwarfed. If the ancient accounts are to be believed giant peoples have, however, existed. Whatever stress we may lay upon this, at the present time gigantism is a sporadic affection. It is a suggestive and striking fact that once the tendency toward gigantism is acquired it is apt to crop out at various times in the same lineal descent, exemplifying the law of atavism. Again it may often be noted that more than one of the children of the same household will be affected. A number of cases might be quoted to illustrate these points. In Dickinson's case (*loc. cit.*) mentioned above, a woman bore three children who weighed nine, twenty, and sixteen pounds respectively. Fuchs' case (*loc. cit.*) was a IX-para. Her sixth child weight 6 kgm., her eighth 6.1, and her ninth 7.55. Her other children had also been heavy. The same thing has been noted by other observers. Goulart refers to a Polish giant who was exhibited in Paris in 1571, and was so tall that in a lofty room he could touch the ceiling with his head. He was married and had a son who promised to be as tall as he was.

James Toller, exhibited in London in 1815, was seven feet nine inches high. His parents were of normal build, but he had two sisters of gigantic stature. Louis Frenz, a French giant, who was born in 1800, and measured seven feet six, had two sisters as tall as he was and one brother who was much larger. The family history of Robert Hales, "the Norfolk giant," is also quite striking. His father was six feet and a half, his mother six feet, in height. One of his ancestors, who lived in the reign of Henry VIII., measured eight feet eight inches. Hales had five sisters who averaged six feet three and four brothers who averaged six feet six. The tallest of the sisters died at the age of twenty, measuring seven feet two. Captain and Mrs. Bates, both over seven feet, had a child which is almost the largest on record. One of the sisters of Chang, the Chinese giant, was even taller than he was, measuring eight feet four.

These facts suggest that this anomaly of growth is due to peculiarities inherent in the germinal cells of the parents. This view is supported by the observations of Engel-Reimers,[19] who has emphasized the fact that excessive muscular development, the so-called "athletic habitus," appears to be due to an abnormal hereditary predisposition and not to hypertrophy from functional overactivity. This is well borne out by the physical condition in new-born giant children. They frequently present the athletic habit. The head is about the size of that of the normal infant, but the trunk is massive. Now this hypertrophy, if we can call it such, is clearly not due to mechanical work nor to compensation, nor to the other ordinary causes of overgrowth. It must be due to some disturbance of nutrition. The relative importance to be attached to peculiarities of the male and female germ cells is still in doubt, for in the recorded cases we rarely have any statement as to the physical condition and development of the father. From the instances cited it is evident that both germinal elements may play a part. But it is equally evident that some idiosyncrasy in the maternal organism alone is sufficient to produce the result. In Fuchs' case, for instance, the father is noted as having been in a poor state of nutrition. This has led Werth to suggest that the tendency to produce large children is due to an inherent peculiarity of the ovum, possibly to its large size. However this may be, we have sufficient evidence to show that large size on the part of one or both parents is not necessary to produce the result in question. Yet it seems probable that physical superiority in the mother, if not in height, at least in physical constitution and nutrition, is an important etiological factor. In 178 cases of large and giant children collated by Fuchs, 166 mothers are noted as being of more than usually strong physical development and nutrition. The remaining 12 were weakly, but in no case did their children exceed 4.36 kgm. in weight, a size which, according to our adopted standard, cannot be regarded as gigantic. In view of this fact we see that the influence of maternal development and nutrition assumes considerable importance. Exceptions to this, however, occur. In a case cited by Dubois, a woman with extensive tuberculosis gave birth to a child weighing 6.336 kgm., and another with severe diabetes had a child of thirteen and a half pounds. Two possibilities must evidently be considered in this connection, a primary peculiarity of the ovum or sperm cell, or both, and a condition of increased intra-uterine nutrition. The influence of peculiarities of the primitive germinal cells would perhaps be best illustrated by instances of the atavistic manifestation of gigantism, or in those cases, like that of Dubois, in which the maternal organism was conspicuously weak, for in the latter case increased intra-uterine nutrition could obviously play no part. Some of the forms of minor terata, such as polydactylism, are no doubt also of this nature. Polydactylism has been known to run through a family for three, four, or even five generations, being eradicated only in process of time by marriage with normal persons. Curiously enough polydactylism has been found associated both with dwarfism and with gigantism. It has been thought by some that mothers in whom the function of menstruation was established early were more likely to have larger children than others, apparently on the theory that such persons were possessed of greater reproductive energy. Negri on the basis of 333 observations has stated that the children of mothers who began to menstruate early were both larger and heavier than the offspring of those whose menstruation was late in coming on. This has not been confirmed, however, by other observers. The point can probably not be decided until more studies on the subject are forthcoming. It is, nevertheless, true, so far as the records go, that large children are more likely to be borne by those who are at the height of reproductive activity and who have had previous children. In elucidation of this point we may perhaps quote Fuchs' statistics. In 176 of his cases, already referred to, the age was ascertained. These were divided as follows: I. Under twenty years, 5; of this number 5 were primiparæ. II. Twenty to twenty-five years, 72; of this number 18 were primiparæ. III. Twenty-six to thirty-five years, 75; of this number 2 were primiparæ. IV. Thirty-six to forty-eight years, 24; of this number none were primiparæ.

Between the ages of twenty and thirty-five, the years of the greatest sexual activity, the number of large children was greatest. Now, taking the third class, we find that only 2.6 per cent. were primiparæ. If these results be compared with those obtained from a series of 1,000 normal births, in 342 of which the mothers belonged to the third age period, it will be found that there were 57 primiparæ, a proportion of 16.9 per cent. This corroborates the observation made a little while ago that certain women show a tendency to produce large children, or in other words that the tendency once manifested tends to perpetuate itself.

Intra-uterine nutrition is undoubtedly a factor of considerable importance. In the article on *Dwarfism* or *Nanosomia* in this volume the rôle played by intra-uterine malnutrition in the causation of inhibited growth is dealt with at some length. Here syphilis, alcoholism, and tuberculosis, together with lesions resulting in interference with the free circulation of blood through the placenta, are of importance. Conversely, an overplus of nutritive energy might be expected to produce its effect upon the fruit. In this connection we have to take into account the condition and surroundings of the mother during pregnancy. Pinard (cited by Bouchacourt[20]) compared the average weight of 500 new-born children whose mothers had worked up to the time of delivery with that of the same number of children whose mothers had rested during the later weeks of pregnancy. He found a notable superiority in weight and nourishment in the offspring of the latter class. In a similar inquiry Bachimont (cited by Bouchacourt) in a series of 4,445 observations found the excess in weight for the latter class of children to be, on the average, 300 gm. In this particular it should be remarked that very large children lead perforce to a condition of complete inactivity and inertia on the part of the women pregnant with them. This of course means rest which tends to increase in turn the size of the child. Thus a vicious circle is induced. The importance of intra-uterine nutrition in modifying the weight of the fruit is well illustrated by the good effect of dieting in those cases in which a woman has either a tendency to produce large children or else has some contraction of the pelvis. By this procedure it has been found possible to deliver such a mother of a living child.

Some attention had been directed to the subject of prolonged gestation and its effect in producing large children. The statistics seem to show that this factor has a certain amount of importance, but it is probably effective only when combined with other causes. It does not seem to me, however, that it is justifiable to place cases of this kind in the same category with giant growth. If, for example, a child is retained within the uterus for three hundred and eight days instead of two hundred and eighty, it is practically in the same position as an infant one month old, due allowance being made for differences between intra-uterine and extra-uterine modes of nourishment. Such a child would derive no permanent advantage from its prolonged retention within the uterus, and would probably develop later much as other children do. In other words, the vitium of excessive growth is not inherent. Unfortunately many of these points we have touched upon cannot be verified by any large series of observations. Gigantism in the first place is much rarer than dwarfism. Then the majority of giant children are still-born. Even those cases in which giant growth manifests itself later in life are beset with difficulties. The number of carefully made studies is not great and prolonged observation is rarely possible, not only from the fact that giants are apt to die early, but on account of their nomadic kind of life.

In dealing with the question of heredity we have adduced numerous facts to show its importance in the causation of anomalous forms of growth. The influence of

factor, while perhaps more direct and striking in the
of giant births, is nevertheless, as we have shown, to
aken into account in the post-natal forms. But be-
s this we have to consider the bearing of internal
abolism on the subject. The more recent work done
retinism and the results of the experimental removal
he thyroid gland have taught us that a condition of
roidea, which undoubtedly acts by perverting the
bolic processes of the organism involved, has a pro-
d effect on the function of growth and development,
ely, in the direction of inhibition. In that other most
rkable perversion of growth, acromegaly, where
are enlargement and deformity of the body, or ex-
ve growth, gross lesions of the pituitary body have
found. Disorders of internal secretion obviously
f some importance.

e general resemblance between acromegaly and
ntism has led to the promulgation of the view that
wo conditions are one and the same thing, and the
oversy over this point has waxed hot and heavy.
out being prejudiced on either side, I think that the
ul observer cannot fail to be impressed with the par-
m which exists between the two affections. Bris-
and Meige have been the chief exponents of the
ity theory, while Marie, who first differentiated
egaly as a disease entity, though he has somewhat
ed from his first position that acromegaly and
tism are entirely distinct, has not been entirely
nced by the arguments adduced against his po-

leton is complete, the soft parts only are involved
get myxœdema. It is unsafe then to conclude
and the same cause may not at times produce
lifferent results. In other words, the trophogenic function of the individual may be so predominant that it is sufficient to alter a morbid state almost beyond recognition. It has already been pointed out that the normal process of growth manifests itself most strongly at the epiphyseal ends of the long bones, and that increase in length of the bones is possible only so long as the epiphyseal discs remain ununited, save by the softer structures, to the diaphyses. Similarly, the abnormal processes of growth, such as dwarfism and gigantism, manifest themselves at the same points. Deficient vegetative energy in early life will result in stunting the growth of the long bones, and the same thing will happen if the epiphyseal cartilages are prematurely ossified. Excessive vegetative power during adolescence results in increase in height; if synostosis of the epiphyses has taken place, as occurs in adult life, then it is conceivable that, increase in length being impossible, increase in breadth and thickness must occur. Do, then, acromegaly and gigantism bear to one another a relationship similar to that existing between myxœdema and cretinism? Many facts point in this direction. Numerous observations have shown that acromegaly frequently supervenes in gigantism. Surmont[23] in 1890 reported a case of acromegaly in a girl of eighteen, in whom the symptoms were preceded by a notable increase in the size of the body. The enlargement was generalized, but most marked at the extremities. Byrom Bramwell[24] mentions the case of a giantess who was attacked by acromegaly. Swanzy[26] also demonstrated the lesions of acromegaly on the skeleton of McGrath, the Irish giant, before the Royal Academy of Medicine of Ireland. Shattock[27] believed the skull of O'Brien to be acromegalic. In 1898 Dana[16] published two cases of acromegaly associated with gigantism, and he remarks that the coincidence of the two affections is more common than has usually been supposed. He further mentions a great many symptoms which they have in common, and brings out the most important point, viz., that out of twelve autopsies on giants the pituitary body was enlarged in ten. In the case of "Adma," a French giantess, who died at the age of twenty-one, measuring six feet eight and a half inches, Hutchinson states[28] that the face and extremities presented the well-known features of acromegaly. At the autopsy the pituitary gland was found to be considerably enlarged. A striking case, also, is reported by Brissaud and Meige.[21] J. P. Mazas, the giant of Montastruc, began to grow rapidly when thirteen years of age, and became very strong and robust. At twenty-one years he was 212 cm. high, eventually reaching 220 cm. At the age of thirty-seven he experienced a severe pain in the back, which he attributed to lifting a heavy weight. Deformity of the back set in and his height began to diminish. He gradually developed enlargement of the face and extremities, headache, weakness, intellectual and sexual torpor, and all the classic symptoms of acromegaly. Sternberg,[29] also, in an elaborate paper on the subject found signs of acromegaly in forty two per cent. of giants. More recently Walker[30] reported an instance of acromegaly in a boy, who began to grow rapidly when six years old, and who at sixteen was six feet five and a third inches high, and weighed two hundred and forty-five pounds. Bonardi[15] refers to the case, already mentioned in another connection, of a boy who at the age of fifteen had the size and development of an adult male. When twenty-two years old he began to suffer from pains in the head and nausea. Soon after, general weakness set in, with enlargement of the hands, feet, maxillæ, and tongue. At twenty-nine he was 194 cm. high and was typically acromegalic. By a careful study of the recorded cases we see, therefore, that a considerable degree of parallelism exists between the two affections. Perhaps the most important points are to be noted in the skeleton.

The typical features in acromegaly are enlargement of the bones of the face and extremities. The hands are "spade-like," and the fingers rounded. In severer cases all the bones of the body become involved. The thorax enlarges and the trunk becomes scoliotic, so that a loss of height takes place. There exist, however, lesser disturbances of bone formation that are difficult to class, being on the border line between gigantism and acromegaly. In such cases the dystrophic disturbance is confined to one or more parts of a member, or to two members symmetrically. Such malformations may be both congenital and acquired. Of such a nature are those cases in which there is deformity of the face without enlargement of the hands. Chauffard[31] reports a case in which a man of thirty-two presented the features of prognathism, macroglossia, prominence of the external occipital protuberance, headache, anæmia, loss of vision to the right, and slight kyphosis. Some of the anomalies, then, that are to be found in acromegaly may be found without the other features of the disease in certain forms of developmental dystrophy, and may arouse a suspicion as to the acromegalic nature of the case. When such peculiarities are met with in giants we may properly inquire whether they are the stigmata of acromegaly, or whether they merely simulate that disease. In giants thickenings of the extremities of the long bones, hyperostoses, and exostoses have been noted, identical with those that for so long have been regarded as characteristic of acromegaly. Deformities of the knees, which as Osborne, Middleton, Schultze, Hitschmann, and Roswell Park have shown, are fairly common in acromegaly, have also been met with in gigantism. Lucas Championnière in 1899 demonstrated to the Academy of Medicine a giant, aged twenty-seven, who measured 208 cm., and presented an extreme genu valgum. This peculiarity has a double interest in that it affords a link between acromegaly and gigantism, and also connects the latter with infantilism. The curvature of the spine and the rounded thorax, so often found in acromegaly, have been found in gigantism, but our information is defective in this regard.

With respect to muscular power great variations may occur both in gigantism and in acromegaly. Several observers, notably Meige, Dallemagne, Virchow, P. Marie, Souza-Leite, Bourneville, and Regnault, have noted acromegaly developing in persons of exceptional muscular vigor. Some giants, like the Emperor Maximin and the Countess Lodoïska, have been of great strength. This, however, seems to be the exception. Geoffroy Saint-Hilaire states that giants are "without activity, without energy, slow in their movements, avoiding work, quickly fatigued; in a word, feeble in body as well as in mind." Amyasthenia and general weakness are by no means uncommon in acromegaly.

As is well recognized there is a characteristic facies in acromegaly. Meige is our authority for the statement that giants who are still in the period of growth present no special facial peculiarities. In those who have ceased to grow there is an exaggerated development of the face as compared with the cranium. We can sometimes note that the malar eminences are prominent, the lower jaw enlarged, and the angle widened, while the lips are thick. The beard is often thin, the skin thick and dark, the pupils dull, and the whole appearance lacks vivacity. These peculiarities are by no means invariable in giants, nor indeed are they so in acromegaly. We have to allow here as elsewhere for individual variations. In fact, we may perhaps with Hoffmann distinguish between acromegaly of the soft parts and acromegaly of the bones.[32] Meige is, on the whole, inclined to believe that the face in giants at one time approaches the acromegalic type, at another the infantile.

Vascular disturbances have been found in both acromegaly and gigantism. In both the pulse is slow, the circulation sluggish, and there may be varices.

Pains in the head have been found in both affections. Pains also in the limbs, vertebral column, and the viscera, have been met with in about half the recorded cases of acromegaly. These may simply amount to a sense of fatigue or lameness, but may be actually articular, muscular, or neuralgic. It is a popular belief that rapid growth in children is associated with "growing pains," and it is interesting that the same thing has often been noted in giants. In the case of McGrath, for instance, the increase in growth was associated with the most violent pains in the limbs.

Visual disorders have been met with both in acromegaly and in gigantism. In acromegaly, at least, they have been found to be dependent on the presence of a tumor of the pituitary body.

Polydipsia, polyphagia, and abundant sweating have been observed in both affections. Polyuria and glycosuria are occasionally met with in acromegaly and in giants who become acromegalic.

In both gigantism and acromegaly there is often to be noted sexual frigidity in the male, and amenorrhœa in the female.

To sum up, the two affections frequently have the following symptoms in common: asthenia in the widest sense of the term; muscular weakness, notwithstanding the absence of atrophy; intellectual degradation; melancholy; headache; diminution of sexual desire in the male; amenorrhœa in the female; alterations in the skin; varices. Lastly, of a great importance, lesions of the pituitary gland have been found in a majority of both affections.

Further, the influence of heredity is marked in acromegaly as in gigantism, and indeed it is not uncommon in probing into the family history to find that acromegaly and gigantism are liable to be met with in the same family. Schwoner, for instance, records[33] a case of acromegaly in a woman of forty-five, whose mother had become acromegalic at fifty. All the members of the family on both sides of the house are noted as having been of great stature. Lackey[34] describes a case of acromegaly in a negro who reached the extraordinary height of eight feet six. His grandfather is said to have been a giant.

In view of the facts outlined above, Brissaud and Meige would discover a general principle underlying the dystrophic disturbances that result in excess. Growth at all periods of life tends to be manifested most conspicuously at the epiphyseal ends of the long bones. The effect produced is controlled by the age of the patient, or, in other words, by his vegetative capacity and the condition of his epiphyseal cartilages. The same pathological process which in the young gives rise to gigantism will, if continued after the normal period of growth in stature is passed, cause acromegaly. If it becomes operative in later youth, when the bones are largely formed but growth is not complete, we get a combination of acromegaly with gigantism. This is to some extent corroborated by the lesions in acromegaly, for, as Marie himself has shown, in cases of acromegaly that begin early in life, the extremities are more elongated than thickened, and are quite unlike the spade-like extremities characteristic of the disease as it occurs in later life. Further, it may be safely stated that acromegaly has never preceded gigantism, while acromegaly has succeeded gigantism in almost half the cases. Brissaud and Meige, however, would go further. They see the same principle at work in the chronic rheumatism so-called of the aged, in rheumatoid arthritis and gout; in youth, in gigantism; in adult life, in acromegaly; in old age, in nodes. They support this by an observation made by Gaston and Brouardel[35] with the *x*-rays on a woman of sixty, who began to show signs of acromegaly at forty-two after the menopause. The disease was slowly progressive, and thickenings in the form of nodules could be made out on the epiphyseal lines.

Without endorsing the rather startling proposition put forth by Brissaud and Meige, that "acromegaly is gigantism of the adult; gigantism is acromegaly of adolescence," it seems to me that the unprejudiced observer cannot fairly deny that they have proved their main contention. There is undoubtedly a close connection between acromegaly and gigantism, and the two affections in a large proportion of cases merge gradually one into the other. Gigantism frequently becomes acromegaly. But how about the other fifty-eight per cent. of cases of gigantism that present no signs of acromegaly? Are these, too, of the same nature, or are they in a different category? It is not impossible nor even unlikely that ome of them are due to the same factors as acromegaly, it is ordinarily understood. Here we have to consider e natural variations of disease. Diseases do not invaably run their course. They may become ameliorated may be aborted. Acromegaly itself may present an tremely slow progression, and in fact may cease to adnce. A fatal termination does not always occur. It y well be, therefore, that acromegaly beginning in rly adolescence may progress only sufficiently far to duce increase in length of bone without the other ns supervening. It may be recalled in this connection t the majority of giants die early. Byrne, the Irish nt, died at twenty-two; James Toller at twenty-four; "Queen of the Amazons" at about twenty. This y perhaps be the effect of the acuteness of their mal-, but in many cases it is due to intercurrent disease, he resisting power of giants is notoriously low. However this may be, it is plain that many giants die before period of age incidence of acromegaly, that is to say, re adolescence is completed. We cannot therefore that they would not have become acromegalic had lived. It is possible, therefore, that the majority he cases of gigantism are dependent on the same ological factors as acromegaly.

ere has been considerable debate as to the exact naof the cause or causes at work in acromegaly. Klebs nced the theory that acromegaly is due to angioma-

Vascular lesions are undoubtedly present both in negaly and in gigantism. Witness the arterioscle- the varices, the vaso-motor ataxia, and the hypery of vessels to adjust themselves to the increased size body. But there is no proof of any new formation ssels. Lancereaux, again, has suggested that it is honeurosis. The enlargement of the hands and the bed innervation met with in syringomyelia might st this. This view is not, however, supported by own facts. von Strümpell has thought that it is a nital dystrophy. The majority of observers are, I practically agreed that acromegaly is dependent ne gross lesion of the pituitary body, in the form ertrophy, cystic growth, adenoma, or other tumor . Osborne believes that gigantism in its perfect pment is due to a normal hypertrophy of the ry gland; that is, to a hypersecretion occurring age of puberty or age of general or symmetrical growth and development. He believes further gantism will remain such as long as the pituitary in normal hypertrophy, but that these cases of sm will assume later an acromegalic type, if, as is e case, the pituitary body begins to take on path- conditions. In other words, he believes that an f normal secretion from the pituitary gland is the gigantism, while perverted secretion is the cause negaly. This conception is very different from Brissaud and Meige, in that it attributes the which we call gigantism and acromegaly, to two and separate states of the pituitary function. and Meige's view implies that the same con- the pituitary function is at work in both cases, rences in the results produced being attributable e period at which the process begins. We know of the nature of the normal function of the body, and indeed of its disturbances, that it hazardous as yet to express an opinion either r my part I cannot understand the term "nor- rtrophy," as applied to the pituitary. We s true, what might be called normal or physi- ypertrophy in the case of the pregnant uterus bly in the functioning breast, yet this is but a condition and is paralled, so far as I know, else in the body. Gigantism is an abnormal and to my mind cannot be explained on the "normal" hypertrophy. It may, however, be it is due to an excess of pituitary secretion. can produce increase in the length of bone, ot also competent to produce increase in thick-? One seems as likely as the other. Whether is due to a hypersecretion on the part of the pituitary, as many seem to think, or to a diminution of the secretion, or again to a perverted secretion, cannot, however, be regarded as settled. Tumors, cysts, and plain hypertrophy of the pituitary have been found in the majority of autopsies on acromegalic cases, and tumors of the pituitary in acromegalic giants (Buday u. Jancto,[36] Oestreich u. Slawyk[37]). Possibly simple hypertrophy or adenomatous growths may imply oversecretion; but cysts or destructive tumors, like the sarcomata that are so frequently found, might be interpreted as lessening the amount of secretion. Conversely, tumors of the pituitary may exist without signs of acromegaly, as in two cases that have come under my own observation. Both were malignant (one sarcoma and one endothelioma). Here we must assume either that the pituitary was able to furnish the proper amount and kind of secretion, or else that compensation had taken place. We are realizing more and more the importance of the principle of compensation in regard to the body metabolism. We see, for instance, that there is a close relationship between the thyroid gland and the pituitary body. In acromegaly the thyroid gland has been found hypertrophied, cystic, or atrophic, and the disease may be complicated by the symptoms of exophthalmic goitre or myxœdema. In this connection may be mentioned a most remarkable case, reported by Pope and Clarke,[38] in which a man suffering from acromegaly had a daughter with myxœdema and an atrophied thyroid, who at the age of twenty presented the physical and mental characters of a child of five. Ponfick, Hymanson, Pineles, and Green, in particular, have noted the association of acromegaly with myxœdema, and Murray[39] its combination with exophthalmic goitre. Conversely, the pituitary has been found enlarged in cases in which the thyroid was atrophied (Boyce and Beadles[40]), and when this occurs it seems to prevent at least the immediate results of thyroid defect, namely, cretinism or myxœdema. In the article on *Dwarfism*, by the present writer, in this volume, the relationship of thyroid dystrophy to that other anomaly of growth allied to gigantism, namely, dwarfism, is dealt with at length, and it is there shown how the condition of athyroidea may result in inhibited growth and genital insufficiency. The stigmata of infantilism in acromegaly and in gigantism have suggested the possibility of disorder of the thyroid in these affections, and there have not been wanting those who would attribute acromegaly to thyroid dystrophy. Facts, however, do not favor this view.

Genital hypoplasia and malformation, as well as genital inadequacy, have been met with in dwarfism, cretinism, infantilism, gigantism, and acromegaly, and this leads us to discuss in how far disorders of the sexual apparatus are responsible for anomalies of growth. In this connection a number of interesting facts may be adduced. The sexual languor, as it might be termed, found in both acromegaly, and gigantism, has been referred to. Garnier and Santenoise[41] have observed a case of gigantism associated with feminism, cryptorchidism, and polysarcia. Thoma[42] mentions having met with defective formation of the genital organs in a case of hemihypertrophy. In acromegaly, as soon as the changes in the bones become manifest, the secondary sexual attributes are changed. In the male the hair becomes scanty, while in the female hair is apt to grow on the face much as it does after the menopause or in ovarian disorders. The larynx hypertrophies and the voice deepens. Infantilism and hypoplasia of the genital organs have also been observed in cases of tumor growth in the pituitary in the absence of signs of acromegaly. Some years ago I performed an autopsy on a woman about thirty years of age who had a perithelial sarcoma of the pituitary without signs of acromegaly, in whom the genital organs were markedly undeveloped. Babinski also reported to the Neurological Society of Paris (June 7th, 1900) the case of a girl of seventeen, who presented the signs of infantilism, amenorrhœa, abundant fat, scantiness of hair, but without acromegaly. She developed pains in the head with disordered vision, and epileptiform convulsions. After death it was discovered that she had a tumor of the pituitary. It is clear then that there is some relationship between lesions of the pituitary and thyroid glands and genital disturbances. What, then, is the primary disorder which leads to such extraordinary anomalies of growth and development? Breton and Michaut[43] have suggested that there is a trophic deviation of the genital activity to the bone marrow so that the medullary bone-forming function preserves its activity indefinitely. The cessation of genital activity would lead to acromegaly. This view is somewhat similar to that promulgated previously by Freund, Klebs, and Verstraeten, who held that there is a disturbance of the evolution of the genital function. If genital evolution is in excess we get gigantism and acromegaly; if defective, we get infantilism and dwarf growth. It is, of course, well recognized that with the onset of puberty the efflorescence of the sexual characteristics is coincident with increased growth and development of the body as a whole. The operation of castration has been observed to exert a notable effect on the stature of the body as well as in inhibiting the development of the secondary sexual peculiarities. In eunuchs the height is often extreme. This is due chiefly to a disproportionate increase in the length of the legs. Lortet has confirmed this statement by an examination of the skeleton of an Egyptian eunuch 196 cm. high. In castrated animals, the capon and the ox, the same increased growth of the lower or hind extremities is to be observed. Silva[44] has further recorded a curious observation in a youth who was normal until the age of thirteen. The testes then remained atrophic and when about twenty he began to grow rapidly, eventually manifesting some enlargement of the head and extremities, muscular weakness, anosmia, slight scoliosis, to such a degree as to suggest acromegaly.

While such facts as those just mentioned are suggestive of some relationship between genital insufficiency and disorders of growth and nutrition, to my mind the evidence is not strong enough to induce us to accept the view that deficiency of the genital organs is the cause of these disorders. Two-thirds of the cases of acromegaly develop after puberty is practically reached. The loss of sexual power in the male is gradual and progresses *pari passu* with the extension of the disease itself. In the female, too, while amenorrhœa is a frequent and often the first symptom of the disease, it is not invariable. Again genital hypoplasia and other signs of infantilism are often present in dwarfs, and the argument might be applied with equal force to explain dwarfism. The same cause could hardly produce at one time dwarfism and at another gigantism. Moreover, while genital hypoplasia has been often observed in cases of thyroid atrophy and gross lesions of the pituitary body, so far as is known castration does not produce a converse effect on these particular organs. While, then, genital hypoplasia undoubtedly plays some rôle in osteogenesis, it seems to be quite a subordinate one, and appears to be inadequate to explain the more marked aberrations from the normal path of development. The functions of the thyroid gland, the pituitary body, and the sexual organs are, however, no doubt correlated, and it is probable that the normal course of growth and development is dependent on a certain balance of power exerted by these glands. Of what nature is this correlation we are to a great extent in the dark. It is generally believed that the glands mentioned produce internal secretions that are essential to the normal course of the metabolic processes. The evidence in favor of this is less strong in the case of the sexual organs (testes and ovaries) than for the other organs. It may be inferred that while the metabolic processes referred to are vital in nature, they are inextricably associated with chemical transformations. The importance of chemical substances in the growth of the organism is well illustrated by the experimental work of Wegner, Maas, and Gies.[45], [46], [47]. Wegner proved that by feeding rabbits with minute doses of phosphorus for a prolonged period he could get a marked increase in the formation of bone at the epiphyseal sutures of the long bones. The same thing has been found to occur with arsenic. Observations upon the nature of the metabolism in giants are hitherto lacking, but we have considerable evidence to show that in acromegaly metabolism is disordered. There appears to be a tendency to an overproduction of lime salts in acromegaly. Deposits of lime have been found in various parts of the body, especially in the pituitary, the thyroid, and the vessels (arteriosclerosis). Ossiform infiltration of the dura mater has been observed. Von Moraczewski[48] has also demonstrated a tendency to the retention of lime and phosphorus in the system in cases of acromegaly. Not only then is there an increased deposit of lime at the extremities of the bones, but also in widely distant parts of the body.

We are, I think, led to the inevitable conclusion that gigantism, like acromegaly, is very often a disorder of development brought about by abnormal metabolic processes. We must also admit that a large proportion of cases of gigantism are etiologically the same thing as acromegaly, and that an additional but uncertain number are probably abortive acromegaly (acromégalie fruste). One consideration must, however, be by no means overlooked in any discussion of the question of internal secretion. The doctrine of internal secretion as at present understood implies the existence of certain substances in the body upon which the secretion of the glands in question may act. Now the gland, thyroid or hypophysis, may be totally unable to perform the duties required of it, owing to some lesion, or it may be only relatively so. In either case similar symptoms would arise. This doctrine of relative inadequacy has been advanced by Prof. J. G. Adami,[49] and has by no means attracted the attention it deserves. On the one hand, relative inadequacy of a gland will set in as soon as its reserve power has been exhausted, and may increase until it becomes absolute. On the other hand, there may be an excess of the substances upon which the internal secretion is supposed to act. Therefore it is quite possible that certain forms of developmental disorder may be due to relative inadequacy on the part of some of the important glands, that, as we have seen, are competent to modify nutritive processes. In the case of gigantism, relative inadequacy of the pituitary, or it may be a relative overadequacy, short of producing the regular symptoms of acromegaly, might influence growth so as to bring about excess.

However this may be, and the deduction is alluring, there still remains some small proportion of cases of gigantism which cannot be explained on any of these theories. Such are the cases in which in addition to excessive height there is great strength with perfect proportion. Here there can be no question of disease in the ordinary acceptation of the term. Such giants are examples of the so-called "athletic" habit of body, and are strictly comparable to the giant infants before referred to. They represent the structure of the human body carried to its highest point. They may be regarded as examples of *true* or *essential* gigantism. Infantilism and pituitary dyscrasia cannot explain them. Rather are they to be referred to peculiarities inherent in the germinal cells of the progenitors. This view is supported by the fact that certain anomalies, for example polydactyly, malformations of the genital organs, and congenital hydrocele, are apt to be associated with the increase in size and weight. *Albert George Nicholls.*

MOLYSIS.—(Synonyms: Hæmocytolysis; Hæma-
; Laking of blood; Globulysis; Erythrocytolysis.)
ough etymologically this term includes destruc-
solution of both red and white corpuscles, yet by
it has come to be applied, when used without speci-
, only to the erythrocytes. When corresponding
s of the leucocytes are considered, the specific term
sis or *leucocytolysis* is generally used. In this
the term hæmolysis will be used, as above indi-
to apply only to *erythrolysis.*
emolysis the essential phenomenon consists in the
of the hæmoglobin from the stroma of the corpus-
o the surrounding fluid. As it is not exactly
in what way the stroma holds the hæmoglobin
y, whether purely physically or in part chemi-
r whether the stroma consists of a spongioplasm
-like membrane, or both, the ultimate processes
mit the escape of the hæmoglobin are not finally
However, the agents by which the escape is
about are well known and extensively studied,
are found to be of extremely various natures.
y be roughly classified as: (1) Known physical
nical agents; (2) unknown constituents of blood
3) bacterial products; (4) certain vegetable poi-
snake venoms.
the known chemical and physical agencies in the
n of hæmolysis have much significance in physi-
d to some extent in pathology, yet the impor-
the subject of hæmolysis at the time of this writ-
chiefly upon the work now being done with
ums; and in turn the chief importance of this
in its relation to problems of bacterial destruc-
destruction, and the general laws of cell sus-
and cell resistance. Hence we shall devote
attention to the subject of serum hæmolysis, appreciating that whether time does or does not show this work to be of as far-reaching importance as is now hoped, yet in any event it will mark a distinct period in the history of medical science. As being by far the simpler, however, we shall first discuss:

(1) HÆMOLYSIS BY KNOWN CHEMICAL AND PHYSICAL AGENCIES.

If distilled water is added to corpuscles of any kind, osmotic changes are bound to occur, since within the cells are abundant salts, soluble in water, which will begin to diffuse outward in an attempt to establish osmotic equilibrium between the corpuscles and the surrounding fluid. Conversely water enters the corpuscles at the same time, and accumulating there leads to swelling until such injury has been produced as permits the hæmoglobin to escape and enter the surrounding fluid. Before this occurred the fluid was opaque because of the obstruction to light offered by the red cells. The stroma now settles to the bottom, while the hæmoglobin diffuses into the fluid, making it red, but perfectly transparent. This process has long been known as the "laking" of blood, and is essentially the condition present in all forms of hæmolysis. That the hæmoglobin escapes only through injury of the stroma and not through simple osmotic diffusion is shown by the fact that if salt solution of the same concentration as normal serum is used instead of distilled water, no such escape of hæmoglobin occurs. As hæmoglobin is perfectly soluble in the salt solution it should pass out if it diffused as do the salts. Since there is no escape of hæmoglobin in such a salt solution, it is evident either that the stroma is not permeable to hæmoglobin, or else the hæmoglobin is in some way attached to or combined with the stroma. Again, if the corpuscles are placed in a solution of salt more concentrated than their own fluids, water escapes and the corpuscles shrink; as no hæmoglobin escapes with the water it is evident that the stroma is not permeable to hæmoglobin when intact. Therefore it would seem that hæmolysis by distilled water may be purely physical, produced by the cell stretching until rupture occurs and the hæmoglobin escapes as from a sac, or else it may be that the stroma is partly soluble in water but not in salt solution, so that the distilled water dissolves the stroma and the hæmoglobin escapes from its attachment. Because of the resemblance of the process of hæmolysis to the rupture of plant cells with escape of their contents when they are placed in distilled water, it might be assumed that hæmolysis is largely a physical matter, but there are many indications that chemical changes must be involved. For example, if a red corpuscle in an isotonic solution is cut into pieces the hæmoglobin does not escape, indicating that its structure is quite dissimilar to that of the simple vegetable cell, and that there is some union of stroma and of hæmoglobin other than physical.

Repeated alternate freezing and thawing is another physical means of bringing on hæmolysis. Heating to 62°–64° C. causes hæmolysis of mammalian corpuscles; in cold-blooded animals this seems to occur at a slightly lower temperature.

Some chemical agents, as might be expected, are capable of liberating hæmoglobin, even when the corpuscles are in isotonic solutions. The ordinary salts of serum, of course, do not have this property, but ammonium salts are strongly hæmolytic. Urea also will dissolve red corpuscles. The chemical agents that dissolve red corpuscles seem to be those that have the power of penetrating the stroma. Ammonium salts and urea penetrate the corpuscles freely and cause hæmolysis. Sugar and NaCl seem not to penetrate the corpuscle, and therefore do not produce hæmolysis. Of the permeating substances there seem to be two types: One, like urea, does not produce hæmolysis when in a solution of NaCl isotonic with the serum; the other, like ammonium chloride, is not prevented from producing hæmolysis by the presence of NaCl. All these agents seem to effect hæmolysis by acting on the stroma, for when the stroma of corpuscles hardened in formalin has its lecithin and cholesterin removed with ether, saponin, a powerful hæmolytic substance, seems to have no effect. The action of saponin and of many other hæmolytic agents can be prevented by the presence of cholesterin in excess, suggesting that it is this constituent of the stroma that is affected. The fact that chloroform, ether, and amyl alcohol will cause laking is probably intimately connected with the fact that lecithin and cholesterin, important constituents of the stroma, are both soluble in these substances. Arseniuretted hydrogen when inhaled causes intravascular hæmolysis, and there are many other drugs and chemicals with the same property, among which may be mentioned nitrobenzol, nitroglycerin, and the nitrites, guaiacol, pyrogallol, acetanilid, and numerous aniline compounds. The bile acids and their salts will also produce hæmolysis, as seen in jaundice. Sodium bicarbonate solutions of one or two per cent. are hæmolytic for some varieties of corpuscles, but 0.1 per cent. Na_2CO_3 and $NaHCO_3$ do not cause hæmolysis.

Leucocytes are dissolved by some of these agents, particularly the bile salts, although they are affected by no means so rapidly or so much as are the erythrocytes. There seems to be no relation between the erythrolytic and leucolytic powers of these substances. Water causes swelling, with solution of the granules in time, and the same is true of ammonium-chloride solutions.

(2) Hæmolysis by Serums.

With these facts as to the physical and chemical properties of the red corpuscles, we may consider the features of serum hæmolysis. Since a very early time it has been known that it is not possible to substitute the blood of animals for the blood of man by transfusion, because the corpuscles of both transfused and native blood soon suffer destruction. Animal experiments also showed that as a general rule the blood of one animal cannot be substituted for that of another of a different species. This observation was not extended, however, until attention was drawn to it later by experimental investigations that may be said to have begun with the observations of Belfanti and Carbone. They found that if the red corpuscles of a rabbit were injected into a horse repeatedly, the serum of the horse became very toxic for rabbits, because it caused dissolution of their red corpuscles. It also developed that this same hæmolytic property was manifested when the serum was added to rabbit corpuscles in a test tube. When Bordet showed the similarity of this process with the solution of bacteria by serum, a process that had already been studied in a similar manner, the phenomenon of hæmolysis by serum suddenly leaped into importance, and has now for some time occupied the attention of a large part of the bacteriologic and pathologic laboratories of the world. In hæmolytic experiments we have a means of studying the property of blood serum of destroying cells under varying conditions, which is extremely easy to observe and control as compared with the less readily examined bacteria or tissue cells. Whatever the future may develop as to their ultimate worth, there can be no doubt that hæmolysis experiments have given us many new and clear conceptions of the means of defence of the body against bacteria, and also of changes in cells of other sorts, that would not have been secured by any other method.

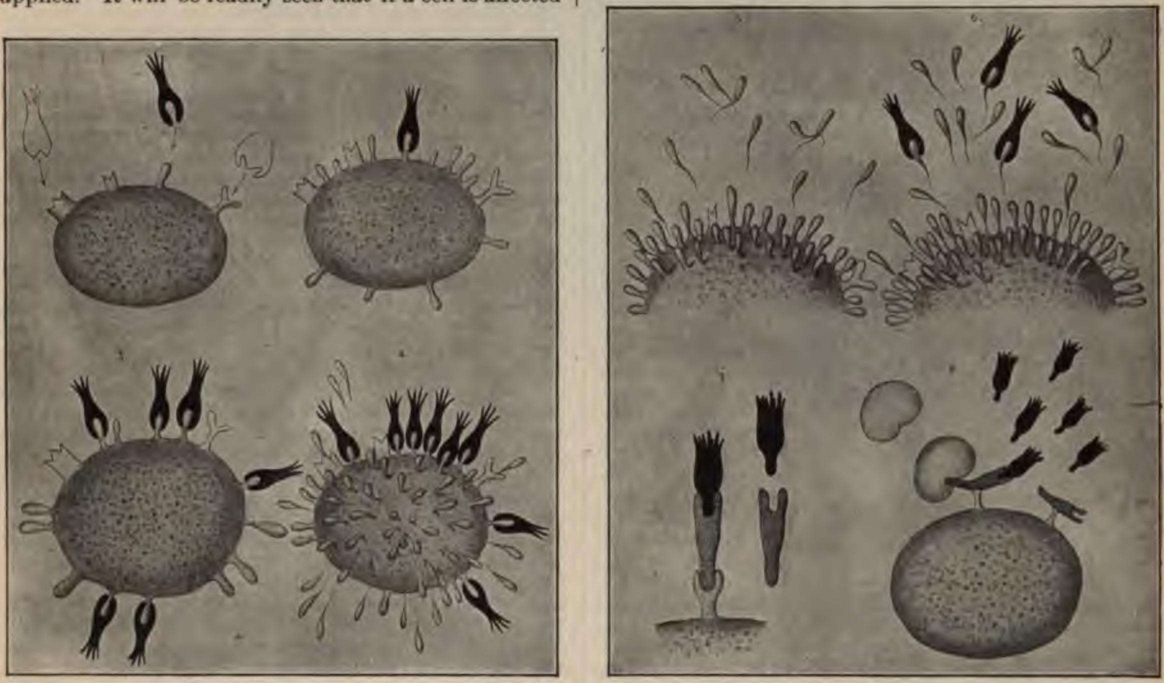
The manner of conducting hæmolysis experiments is usually about as follows: Blood corpuscles of the kind to be tested are secured by defibrinating the freshly drawn blood in the usual way, by whipping. A five-per-cent. solution of these corpuscles is made by adding 19 parts of 0.75 per-cent. NaCl solution, which is isotonic with them. This emulsion is placed in test tubes, very small ones by choice in order to save material, and the serum that is to be studied is added to it. It is necessary that the tubes be cleaned as for chemical research and sterilized, and all steps of the experiments should be under aseptic precautions to prevent bacterial action affecting the experiments. As Jordan has shown that even the degree of alkalinity possessed by some varieties of glassware when new may cause hæmolysis, the tubes should be cleaned with the usual acid-cleaning fluid. The tubes, stoppered with cotton, are kept at 37° C., and in the course of from fifteen minutes to two hours the hæmolysis will be manifested by the diffusion of the hæmoglobin upward into the supernatant fluid, while the turbidity produced by the red corpuscles disappears. At the bottom of the test tube the stroma collects as a slight sediment.

The Mechanism of Hæmolysis.—If a serum from an animal immunized against the red corpuscles of another animal is allowed to act upon such red corpuscles in a test tube, hæmolysis occurs promptly. Bordet showed that this property was lost if the serum was heated half an hour at 55° C., indicating that the destroying agent was very sensitive to heat. In addition he found that if to such heated serum, deprived of all hæmolytic power, there was added a small amount of serum from an animal that had not been immunized and which was of itself inert, the combination was quite as active as the unheated immune serum. In other words, there is contained in normal serum a substance easily destroyed by heat, that needs to be present to cause such specific hæmolysis. But this *thermolabile* substance alone is not able to dissolve the red corpuscles, as the normal serum is found to be quite inactive; it is necessary also to have present some second substance that appears in the serum during the process of immunization. And as heated serum is also quite inactive it is apparent that this heat-resisting (*thermostable*) substance is not of itself able to dissolve the corpuscles. Therefore evidently two substances are needed to dissolve the corpuscles: one, which is easily destroyed by heat and which is present in normal serum; the other, which is present in sera of immunized animals, and which resists heat. Before Bordet had demonstrated these facts about the red corpuscles he had found out that the same conditions prevailed in the destruction of cholera spirilla by the serum of animals immunized against them—two similarly behaving bodies are required in the solution of the organisms, the so-called "Pfeiffer's reaction." Out of these fundamental observations have grown the vast amount of research on serums in their relation to immunity, and on them have been based the theory of Ehrlich as to the ultimate nature of the processes of bacterial and cellular destruction that protect the body from infection and disease, and which perhaps play a part even in normal metabolism.

Ehrlich's Theory of Hæmolytic Processes.—Although at this time Ehrlich's ideas stand only as theories, and nothing more, still the fact that they have given us some sort of mental image upon which to base investigations of undoubted value, places them in a certain position of permanence. For this reason we shall endeavor to set them forth briefly in this article.

The Nature of Toxin and Antitoxin.—The fundamental feature of Ehrlich's theory rests upon a conception of the manner in which a toxin attacks a cell. If we consider a cell purely as a mass of various chemicals, and a toxic material as another chemical substance, either simple or complex, it will be apparent that the toxic substance will affect the cell if there is a chemical affinity between them. If there is no such affinity that particular toxic substance is not harmful for that particular cell. On the other hand, if the toxic substance and the cell do possess a chemical affinity they will unite, and the composition of the cell will be altered. When the uniting substance is toxic the result of the union is an injury of some kind to the cell. Undoubtedly other substances may unite with the cell without injuring it, for example, food supplies.

If this line of reasoning be carried still further, it will be readily seen that of the many substances of different chemical nature that compose a cell, not all can have the same degree of affinity for the toxin. By ordinary chemical laws the substance that has the greatest affinity will attract the toxin until it is saturated, and only on condition that there are other substances with affinity of varying degrees will more than the one susceptible substance unite with the toxin. We can thus conceive of



FIGS. 5153 and 5154.—Ehrlich's Diagrams Illustrating the Mechanism of Immunity and Cytolysis. 1, 2, and 3 illustrate different forms of receptors, showing the necessity for agreement of the combining bodies. The figures in black indicate substances with toxic action. 4, 5, and 6 illustrate the excessive production of receptors in response to the action of toxins, and their escape from the cell; in 6 they are seen to combine with toxin outside the cell, preventing its union with the cell; 7 shows the structure of the complement and intermediary body of bacterolytic and cytolytic sera; 8 shows the amboceptor, while attached to the cell, uniting the complement to a large molecule.

a cell with one or more constituents that may become united to any given toxin with varying readiness. To these cell components that combine with the toxin the name *receptor* has been given by Ehrlich, and is generally applied. It will be readily seen that if a cell is affected by a toxin that fact implies the presence in the cell of a receptor for the toxin. Conversely an absence of proper receptors will explain the lack of susceptibility of certain other cells to the same toxin. For example, we may consider that some animals are immune to tetanus because the cells of their nervous systems contain no receptors that will combine with the tetanus toxin. To make the analogy to chemical reactions, Ehrlich has likened the receptors to the various *side chains* of organic compounds.

Figs. 5153 to 5157 represent in diagrammatic form the principles involved, in which definite forms are made to indicate chemical groups, and differences in their configuration to indicate differences in chemical affinity. The protrusions from the cells indicate the receptors or "side chains" that combine with outside substances. Each particular variety of receptor combines with the particular toxin for which it has a chemical affinity, as indicated by correspondence of configuration. In these diagrams toxic bodies are always indicated in black; and the black objects represent toxins which combine with the particular receptors they fit, or, in other words, for which they have a chemical affinity.

The body known as antitoxin is evidently one that has the power of combining with the toxin, for it has been demonstrated repeatedly that mixtures of toxin and antitoxin in proper proportion that have stood together a short time are quite inert; the union seems to be after the nature of the union of chemicals. This fact likens antitoxin to the receptors which have just been described, and in fact it is considered that antitoxin and receptor are identical substances, with the difference that the receptor is a part of a cell, while the antitoxin exists free in the serum. Ehrlich's explanation of the formation of antitoxin is as follows: When the toxin combines with the receptors of a cell, the cell is deprived of these receptors for whatever use they may have under normal conditions. Obeying the laws of regeneration the cell replaces these lost groups by new ones; indeed it replaces them in excess, much as in the healing of a wound there is an excessive formation of new cells. The excessive receptor bodies fall away from the cell into the serum, where, if they meet with any toxin, they will combine with it just as well as if they were still attached to the cell. Of course if the toxin is saturated with receptors while in the serum, it is devoid of any affinity for the receptors attached to the cells and does not harm the cells. In this way the cells are protected from the toxin. So, when we inject diphtheria antitoxin into the body of a patient, we are merely introducing receptors from the susceptible cells of a horse. These meet with the molecules of diphtheria toxin while it is still in the blood, and combining with it there prevent it attaching itself to any of the cells of the patient, and so it is rendered incapable of causing harm. The diphtheria antitoxin is not only able to combine with diphtheria toxin which is in the circulation, but if in excess to wrest from the cells toxin which may have already been combined, probably by the law of mass action. This always happens when a case of diphtheria is cured by

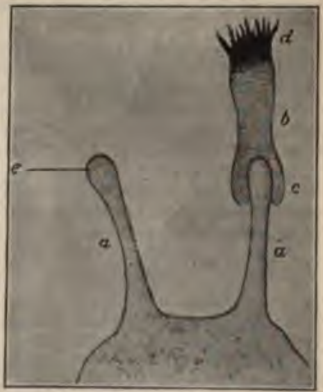


FIG. 5155.—Receptor of the First Order (*a*). *e*, Haptophore complex; *b*, combined toxin molecule, with haptophore (*c*) and toxophore (*d*) groups. (After Ehrlich.)

antitoxin, and the clinical evidence of the "wresting" process is the sudden subsidence of the disease. It is not so easy to wrest tetanus toxin from the nervous tissue with antitoxin, and accordingly tetanus is not often cured by antitoxin.

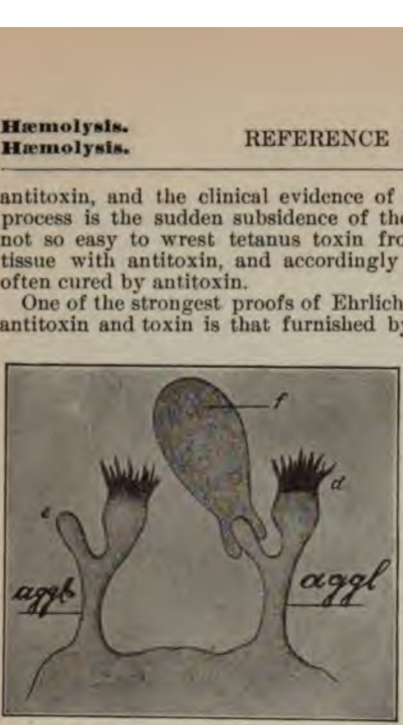

FIG. 5156.—Receptor of the Second Order (*aggl*), with haptophore (*e*) and zymophore (*d*) groups; *f*, combined food molecule. (After Ehrlich.)

One of the strongest proofs of Ehrlich's conception of antitoxin and toxin is that furnished by Wassermann's experiment. This consists in permitting tetanus toxin to stand for some time in contact with nervous tissue; it will then be found that the fluid part has lost all of its toxic property, and further, that the cellular portion which presumably contains the toxin is also not toxic. This agrees fully with Ehrlich's idea that a toxin attacks the cells that have receptors for it, and when so combined is harmless for other cells. In this case the nerve cells have combined with the toxin just as does antitoxin and have rendered it unable to attack other nerve cells. Other tissues are found to be quite unable to fix tetanus toxin in this way. A similar action has been found by Flexner to exist between nervous tissue and the specific nervous poison of cobra venom. The union of toxin and antitoxin seems to be of strictly chemical nature, for it follows the usual laws of chemical union, and it seems impossible to separate again the toxin and antitoxin after they have combined.

No. 4, of Fig. 5153, and No. 5, of Fig. 5154, illustrate the overproduction of receptor groups, which are liberated and enter the blood plasma. No. 6 (Fig. 5154) indicates the combining of the receptors with the toxin molecules, and shows how incapable they now are of combining with the cell.

In the process of immunization, under this conception, the receptors of the cells are repeatedly combined with toxin, and the resulting reaction on the part of the cells causes the discharge of large numbers of free cell receptors into the blood. These receptors give the serum whatever antitoxic property it may have.

The Structure of Toxins.—We have referred to the fundamental conception of a toxic substance as a substance which by combining with the receptor of a cell injures the cell in some way. It has been developed that toxin accomplishes this injury by a portion of itself that is different from the portion that combines with the receptor. In other words, a toxin consists of a substance that binds it to the cell, and of another that causes the injury to the cell. This may be explained best by describing the facts that gave rise to this idea. When a toxin, say tetanus toxin, has been kept for some time, it is found that its toxic action decreases until relatively very large amounts are required to produce symptoms of tetanus in animals. Such a weakened toxin, however, requires just as much antitoxin to neutralize its toxic action as it did while possessed of its full strength. As the antitoxin is merely an accumulation of free receptors, it seems that the toxin during the process of weakening has lost none of its power to unite with receptors, but rather has lost its power to cause injury to the cell. The group that attaches itself to the cell receptor has been called by Ehrlich the *haptophore* group, while the group that injures the cell is called the *toxophore* group. Toxins that have become weakened while still retaining their power to combine with antitoxin are referred to as *toxoids*, and are supposed to be toxins that have lost the toxophore group but have retained the haptophore group. In the diagrams of Ehrlich the fringed portion of the toxin figure represents the toxophore portion; the part fitting with the receptor, the haptophore.

It may be mentioned that this degeneration of toxins into toxoids has practical application in immunization, for since toxoids are just as capable of combining with cell receptors as are toxins, they can be used to produce antitoxin without danger of causing intoxication.

The Relation of Toxins to Hæmolysins.—While the above discussion of the nature of toxin and antitoxin does not directly apply to the subject of hæmolysis, yet it is necessary to an understanding of the principles of cytolytic phenomena, since out of this conception of the nature of immunity against toxin has come our present conception of the nature of immunity against cells. Animals are immunized against foreign blood corpuscles just as they are against bacteria and against toxins, by repeated injections of small amounts of the foreign substance. Similarly in each case their serum comes to contain a substance capable of protecting the animal against the injected material. However, there is one important difference between immunity against toxin and immunity against cells, whether these cells are bacteria, blood or tissue cells matters not. To neutralize a toxin it is merely necessary to occupy the group of the toxin that unites with the cell receptors, for then the toxin cannot unite with the cells to injure them; in this harmless condition the toxin is destroyed or eliminated. In the case of the cells, however, it is necessary that they be destroyed by the serum, and this requires more than the entrance into them of some body from the serum; they must be attacked somewhat in the way a toxin attacks a cell. In fact, a serum immunized against a cell is really a toxin for that cell, and like the bacterial toxins it possesses two groups, one combining with the cell, and the other that attacks the cell. However, there are certain important differences between bacterial toxins and immune serums. It will be remembered that it was found that both bacteriolytic and hæmolytic serums lost the power of producing their specific effects of cell destruction when heated for half an hour at 55° C., and that they regained this power in full when to them was added some normal serum, which alone was quite inactive. From this it was deduced that two substances enter into the cytolysis: one susceptible to heat and present in normal serum, the other more resistant to heat, and present only in immunized animals. Comparing the cytolytic serum with the toxin we see that the chief difference lies in the fact that one of the cytolytic bodies is present normally in the serum, and can be supplied quite readily to make the other body active. In its susceptibility to injurious agents and in its power to

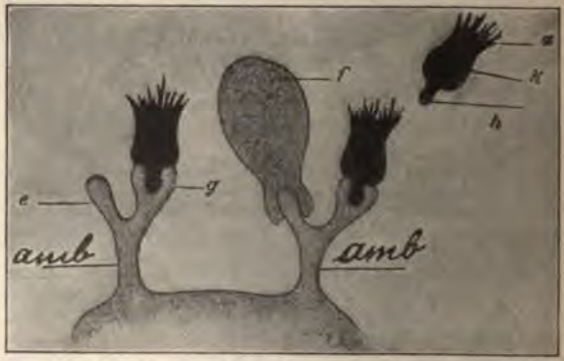

FIG. 5157.—Receptor of the Third Order. *amb*, The receptor; *e*, haptophore (cytophile) group; *g*, complementophile group; *K*, complement, with haptophore (*h*) and zymotoxic (*z*) groups; *f*, combined food molecule. (After Ehrlich.)

destroy cells this thermolabile substance resembles the toxophore group of the toxin. As it has to be added to the body that is developed during immunization to render the latter active, it has been given the name of *complement*, indicating that it is a complementary substance in the reaction. Another name sometimes applied to the same body, *addiment*, is of similar significance. On the other hand, the body developed in the serum through the process of immunization, is quite like the haptophore group of the toxin, in that it is more resistant to injurious influences, and, as will be shown later, is concerned in uniting the complement to the cell to be attacked. As it has two affinities, one for the cell, the other for the complement, it has been called by Ehrlich *amboceptor*, implying the double affinity. A receptor, for example, having but one affinity may be called a *uniceptor*. Another name commonly given to the amboceptor is *immune body*, because it is the specific substance that confers immunity; but, as this or a similar body may be naturally present in the serum of animals that have not been immunized, this name can be used only for specifically immunized animal serum, and the more general term, *intermediary body*, is used except in specific instances.

The Mechanism of Hæmolysis.—Our understanding of the phenomena of hemolysis is therefore as follows: During immunization the immune bodies are developed, which have the property of combining with the red cells, attaching themselves to the receptors of the corpuscles. They combine on the other side with the complement that is present normally in the serum, even before immunization, and by so attaching it to the corpuscles enable it to exert its destructive action. This arrangement is indicated by No. 7 (Fig. 5154), in which the black fringed body represents the complement, united by the amboceptor to the red cell receptor. Beside it are shown free the two constituents of the hæmolysin. Without being attached in this way the complement is quite inert. That the immune body is attached to the corpuscles is shown by the following experiment: If an immune serum is heated the complement is destroyed, and we have the immune body in an inactive condition in the serum. This inactive serum is mixed with red corpuscles, and kept for fifteen minutes at 45° C.; the red corpuscles are then separated by centrifugalization. The supernatant fluid is removed and added to other red cells. If it still contains intermediary body it should be able to dissolve the corpuscles when fresh normal serum, containing complement, is added. As no hæmolysis does occur it appears that all the intermediary body has been taken out of the serum by the red corpuscles. That this is the case can be proved by adding to these corpuscles some normal serum which contains complement, but no intermediary body, for the corpuscles are now quickly dissolved. Therefore all the intermediary body must have been united to the red corpuscles during the fifteen minutes' exposure at 45° C. Another demonstration of this is made as follows: If just enough red corpuscles, heated immune serum, and fresh normal serum are mixed at 0° C. in the proportions required to saturate all the affinities and to leave nothing over, on removing the corpuscles it will be found that all the complement is in the supernatant fluid, and all the intermediary body is attached to the corpuscles. This indicates that the affinity of the intermediary body for the receptor of the corpuscle is greater than its affinity for the complement, and also shows that at 0° C. the complement and intermediary body can exist side by side without combining.

The foregoing are the fundamental facts concerning the mechanism of hæmolysis, and the facts themselves are generally accepted. However, there are those who oppose the theory advanced by Ehrlich in explanation, contesting it on various grounds. For instance, by some it has been thought that the intermediary body acts after the manner of a mordant, simply modifying the cell so that it absorbs the complement, and all the features of hæmolysis are considered manifestations of physical rather than of chemical action. Nevertheless, at the time of writing it has been possible to fit all the facts that have been developed into accord with the theory, and there is no question that the theory has been of immense value in giving a ground from which to proceed in new investigations of the laws and processes of immunity. In defending the theory, however, it has been found necessary greatly to amplify and modify the original simple conception stated in the preceding paragraphs; and, as this process is still going on, it will be impossible here to give a complete account of all the changes so made. Considering each by itself, we shall make an attempt to give the chief facts concerning the two agents in the hæmolytic process.

The Intermediary Body.—This factor in the cytolytic process has had an unfortunately large number of names applied to it, leading to much unnecessary confusion. Immune body and amboceptor have already been mentioned and explained. French writers often use the term, *substance sensibilisatrice*, with the view that its action is to prepare the corpuscle for the action of the complement. Rarely used now are the terms *fixator*, *desmon*, and *copula*. In general the name "intermediary body" (German, *Zwischenkörper*) is to be preferred, unless we are dealing with a specific substance obtained by immunization, when the term "immune body" may be used.

Its exact nature is totally unknown, for it has not been found possible to isolate it from other constituents of either serum or blood corpuscles. The fact that it is generally deprived of its action at about 70° C. would suggest that it is either a form of proteid or is combined with one. However, thermolabile intermediary bodies have been described; like the complement they are destroyed at a lower temperature. The intermediary body does not seem to develop an affinity for the complement until it has first combined with the cell.

In immunization the body is formed in large quantities, much as is the antitoxin. As a rule the greater the difference in the nature of the animals used the greater the activity of the resulting serum. Rapid absorption of large quantities of corpuscles is also desirable, to which end the blood is usually diluted with an equal quantity of 0.75-per-cent. salt solution and injected intraperitoneally. Ehrlich explains the formation of the immune body on the same basis as the antitoxin formation is explained. In its ordinary processes of nourishment each cell must combine with proteid molecules so large that in comparison with them the toxin molecules are small indeed. Such giant molecules cannot be used by the cell as they are, but are made available by means of a ferment-like process which splits them up into smaller fragments. This act is pictured as being accomplished by a group attached to the cell, which has one arm with affinity for the proteid molecule and another for the ferment (see No. 8, Fig. 5154). In this way the proteid molecule and the ferment are united in order that the proteid may be acted upon. It will be seen that this is merely an amplification of the idea of the toxophore group of the toxin, which is attached to the cell by the haptophore group, in order that it may produce its injurious effects. In hæmolysis the red corpuscle is considered in the place of the proteid molecule, and in immunization against red corpuscles we simply have large quantities of such "side chains" as have this double affinity for corpuscle and ferment, cast off in numbers into the plasma. These side chains, then, are the intermediary bodies, which by the nature of their affinities are able to unite the complement to the red corpuscles and to accomplish their destruction.

Normal serum may contain bodies with the same properties as the immune bodies. For example, dog serum has normally considerable hæmolytic action on guinea-pig corpuscles, and human serum on rabbit corpuscles. That this is due to the action of a true intermediary body is shown by the fact that when the serum is heated and the dog complement is destroyed, normal guinea-pig serum when added will furnish complement and hæmolysis will occur. This also indicates that one particular intermediary body may unite with more than one sort of complement, for in this instance guinea-pig complement has taken the place of dog complement, and has united with amboceptors from dog serum. So far as we know, all varieties of animals may produce hæmolytic amboceptors. Noguchi has demonstrated their presence, both normally and after immunization, in both vertebrates and invertebrates.

It is to the immune body that the specific action of immune sera is due. This may be shown by placing both chicken and guinea-pig corpuscles in a drop of serum from a rabbit immunized against chicken corpuscles. The nucleated corpuscles of the chicken can be readily distinguished from the corpuscles of the guinea-pig, and it will be found that they undergo hæmolysis, while the guinea-pig corpuscles do not. It may also be mentioned that in this process the nuclei of the corpuscles are not dissolved, only the cytoplasm containing the hæmoglobin being noticeably affected.

On the other hand, it is possible for a serum to contain at the same time a large variety of hæmolytic amboceptors. These may be present normally, in which case the serum has the power to dissolve many varieties of corpuscles; or the same effect may be obtained by immunizing the animal with several varieties of blood at the same time. It has been shown that here we have not one amboceptor capable of uniting with all the varieties of corpuscle, but rather there is a special amboceptor for each variety. If one is removed by saturating with one sort of red corpuscle, the serum can still dissolve all the other sorts.

Another interesting feature of the immune body is that animals may be able to produce a body hæmolytic for other individuals of their own species; for example, a goat immunized against the corpuscles of another goat may have its serum become hæmolytic for the corpuscles of that particular goat. Such a lysin is called *isolysin*, as contrasted with the *heterolysins* formed when animals of different species are used. Of great importance is the fact that an *autolysin*, that is, a body causing hæmolysis of the corpuscles of the animal providing the serum, has not been obtained, although many experiments have been made to this end. It can be readily understood what serious results would promptly arise if such autolytic bodies were formed, and it has naturally been suggested that such a condition may exist in certain instances of auto-intoxication. In various diseases, moreover, Eisenberg found that *isoagglutinins* were present in very variable quantities, yet there were no instances in which the individual's serum was hæmolytic for his own blood. It must be admitted that at present the reason for the absence of autolysins is not satisfactorily explained.

The time required for the development of immune bodies varies greatly, as also does the time of persistence after immunizing injections are stopped. In some instances hæmolysins may be found as soon as a day after injection of corpuscles for the first time, and they are usually present in a week. In certain experiments of Ehrlich the time when maximum activity of the serum was reached varied from seven to fifteen days.

Bordet and other French observers have claimed that the union between amboceptor and corpuscle is not chemical but purely physical, but this contention seems to have been quite completely answered by Ehrlich and his followers. Ehrlich illustrates the resemblance of the reactions of intermediary bodies to known chemical substances by a comparison with diazo-benzaldehyde. By means of the diazo group the benzene radical may be united to one set of substances, such as phenols, aromatic amines, etc., while by the aldehyde group a different set of substances can be combined, including ammonia radicals and HCN. Thus by having the diazo-benzaldehyde as an intermediary body phenol and HCN can be united, the phenol in this case assuming the place of the red corpuscle, and the HCN the place of the complement. In any event it seems certain that the union of the immune body is with the stroma alone, and as physical means have been found inadequate to cause the liberation of the hæmoglobin it is apparent that some chemical change results.

Of the two combining portions of the amboceptor, the one that has an affinity for the complement is referred to as the *complementophile* group, while the one that unites with the cell is called the *cytophile;* or, in the case of hæmolysis, as the *hæmophile* or *hæmotrophic* group. It seems probable that there are also intermediary bodies that have several combining groups, and are therefore not amboceptors, but triceptors, quadriceptors, etc.

By those who consider phagocytosis of particular importance in all processes of immunity, the observations of Savtchenko, that the immune body causes the phagocytes to engulf corpuscles with great readiness, is esteemed of much significance. This increased phagocytosis is manifested by leucocytes either in the body or in the test tube, and may explain, at least in part, the increased phagocytosis observed in many diseases. Whether the phagocytosis is increased because of alterations in the red cells, rendering them more chemotactic than normal, or to direct stimulation of the phagocytes, is unknown. The former seems more probable.

Immune bodies are capable of transmission from mother to fœtus, although there is no transmission from the male parent. A rabbit immunized before or during pregnancy to certain corpuscles may give birth to young possessing similar immune bodies, and it is possible for immune bodies to be transmitted by the milk. Normally existing hæmolytic and agglutinating properties may be transmitted from mother to fœtus, but they do not necessarily agree in proportion in the blood of each; they are usually less in the fœtus.

Complement.—Because of its property of causing solution phenomena in cells, whether corpuscles or other kinds, complement is generally considered as of the nature of a ferment, and this is supported by its susceptibility to heat, which is much the same as that of the known proteolytic enzymes. Many chemical agents, such as ten-per-cent. HCl, also destroy complement. Furthermore Delezenne has shown that the union of trypsinogen and enterokinase in the intestine, that results in the production of the active proteolytic ferment trypsin, is of exactly similar nature to the union of complement and immune body. On the other hand, after hæmolysis of red corpuscles no bodies are found that agree with those produced by either tryptic or peptic digestion, and the stroma is not ordinarily dissolved, but is deposited at the bottom of the test tube as a sediment, still retaining some of its original form. In solution of red corpuscles by the known proteolytic enzymes the hæmoglobin is attacked and much altered, while it is unaffected in serum hæmolysis. Again, the hæmolysin differs from a ferment, in that definite quantities of complement dissolve definite quantities of corpuscles, and do not have unlimited action as do the ferments; therefore it would seem that the complement enters into combination in the reaction, which ferments do not do.

The origin of the complement is unsettled, although there is much reason to believe that the leucocytes are one source, and perhaps the chief one. The complement content of peritoneal fluid seems to be increased if many leucocytes undergo dissolution in it, and this fact was the basis of the idea of a bactericidal substance, *alexin* (Buchner), that the leucocytes secreted. Ehrlich seems to have demonstrated that this alexin is the same as the immune body and complement, and not a single substance that by itself destroys bacteria. Aseptic inflammatory reactions have been found to increase both the bacteriolytic and hæmolytic complement of the blood, although it cannot be demonstrated that the exuded leucocytes are rich in complement. It has also been found that the complement content of the blood in disease varies often in direct ratio to the amount of leucocytosis. Removal of the spleen does not prevent either the presence of complement or the formation of immune bodies in experimental animals (Levin). Complement is present in the serum of cold-blooded animals.

Undoubtedly there is more than one sort of complement, although at first Ehrlich thought that the complement was one and the same for all cytolytic processes. In some sera saturation of all the complement possible with one variety of amboceptor still leaves the serum

ontaining complement that can dissolve corpuscles when
he proper amboceptors are supplied. Again, serums
ave been found to possess complements with varying
esistance to heat, some being indeed quite thermostable.
n one serum, for example, immunized against a mixture
f swine, sheep, and ox blood, Wendelstadt found that
he complement for swine blood was more resistant to
eat than that for ox or sheep blood, while the latter re-
isted HCl more. Normal horse serum was shown by
hrlich to contain two complements: one specific for
abbit corpuscles, the other for guinea-pig corpuscles,
hich could be separated by filtering through a Pukall
lter, as the guinea-pig complement alone passed
rough. This variability in filtration of complement in-
icates that the size or consistence of the molecules is not
issimilar to that of the enzymes, which are also vari-
sly held back by filters. Some complements have been
und to diffuse through animal membranes, while others
not. It therefore seems that complement is not, as
as at one time believed, a single, non-specific substance,
t complements may be as numerous and as various
the intermediary bodies. However, one thing seems
oved, namely, that the complement is not developed
rough the process of immunization, but is a constant
nstituent of the normal serum, although greatly fluc-
ating in quantity. In immune serum, as a rule, the
ount of complement is inadequate to saturate the
mune bodies present. As before mentioned, this defi-
ncy may be met by adding serum from animals not
munized—serum which contains complement. As a
e the normal serum should be from an animal of the
ne species as the immune animal, but it is a remarkable
t that a proper complement may be obtained for im-
ne serum of one animal from an animal of an entirely
ferent species. For example, serum of a dog immun-
d against the corpuscles of a guinea-pig, after being
dered inactive by having its complement destroyed
heat, may be again activated by addition of normal
nea-pig serum; that is, the guinea-pig complement
l unite with the dog immune body as well as will the
plement from the dog.

nother important fact concerning the varieties and
ure of complement has been furnished by Kyes, who
onstrated that red corpuscles may contain within
nselves intracellular complements, *endocomplement*.
qual significance is the related observation that *leci-*
will act as a complement for cobra poison. That a
nite substance of known chemical composition may
as the complement is an important step, although
hin must be more allied to thermostable comple-
ts than to thermolabile complements, which are the
seemingly of most importance.

here are two groups in complement: one of which is
ed to the immune body, therefore a haptophore
p, and another that acts upon the cell to which it is
ored, and called the *zymotoxic* group. This latter is
gous to the toxophore group of a toxin. As a mat-
f fact a complement is a toxin for the cell it may
k. As might be expected, therefore, just as toxoids
ormed by degeneration of the toxophore group of
toxin, so also *complementoids* are formed by the de-
ration of the zymotoxic group of the complement.

before mentioned, the affinity between complement
ntermediary body is less than between intermediary
and cell receptor, therefore the latter union occurs

If the amount of intermediary body is largely in
s of the amount of complement the hæmolysis is
ly interfered with, because the excessive inter-
ry bodies unite with the complement; and as the
eceptors have all been at once occupied by inter-
ry bodies, the complement cannot become attached
cell, since intermediary bodies do not unite with
other. This blocking off is referred to as *deviation*
complement.

generation of complement after it has been exhausted
place in a short time. In rabbits whose serum was
ved of complement by injecting goat corpuscles
the complement had all been absorbed by them, it was found that complete regeneration may take place in from two to four hours.

Although the complement is the normal, constantly present constituent of the blood that probably protects the body against bacteria and other injurious agents, yet it is also capable of being harmful to the cells of its own creator. Snake venoms, for example, seem to owe their poisonous properties to the presence of large numbers of amboceptors of various sorts, and therefore to produce their violently injurious effects they require the action of complement, which is furnished by the poisoned individual for his own destruction. It is probable that there are other conditions in which the complement is an agent of harm rather than of protection.

The amount of complement in the serum of an individual varies in health, and even more so in disease. In phosphorus poisoning the power of the serum of the rabbit to destroy guinea-pig corpuscles is lost, because the corresponding complement is absent. Longcope claims that complement for typhoid and colon bacilli is decreased in many chronic diseases, which may account for terminal septicæmia. Alcoholism is also said to reduce the complement of the blood of animals. Undoubtedly the fluctuation of complement content of the blood is an important factor in determining susceptibility to infection.

An indication of how purely chemical is the union between the various substances implicated in hæmolysis is the observation by Hektoen that ions of Ca, Sr, Ba, and SO_4 combine in such a way with complement that it is unable to unite with the immune body, and thus they prevent hæmolysis. These inorganic substances seem to saturate the affinity of the haptophore group of the complement in the same way that amboceptors do.

Antihæmolysin.—Just as an antitoxin can be produced by immunizing cells against the toxins that injure them, so by immunizing the blood corpuscles against hæmolytic serum an antihæmolytic serum can be obtained. If heated serum is used an anti-immune body is obtained, that acts by combining with the cytophile group of the intermediary body and thus preventing the intermediary body and the corpuscles from uniting. If there are several intermediary bodies in the injected serum, antibodies may be obtained that are specific for each. These antibodies seem to be the receptors of the red cells that unite with the intermediary body in producing hæmolysis.

By immunizing against normal serum, whether heated or not, *anti-complement* is obtained which also is specific. Ehrlich has shown that this anti-complement acts by combining with the haptophore group, thus preventing the complement from being anchored to the cell by the intermediary body. Such anti-complement does not unite at all with the intermediary body, which remains in a condition capable of taking up fresh complement if it is provided. Again, resembling the production of antitoxin with toxoids, anti-complement can be obtained by immunizing with complementoid.

Not only can *anti-heterolysins* be obtained, but also *anti-isolysins*, if serum hæmolytic for blood of an homologous animal be used in immunizing. Since during normal conditions of life red corpuscles are continally undergoing dissolution, it may be that in everybody there really develop autolysins, which are prevented from causing extensive destruction of the corpuscles by the production of *anti-autolysin*. Besredka seems to have demonstrated the presence of such antibodies in normal serum, and suggests that such self-immunization may be an important process in protection of the body. In this connection it may be mentioned that there seem to be antiferments normally present in the blood that are perhaps of importance in preventing self-digestion of the tissues during life by the ferments of the body itself.

Agglutination in Relation to Hæmolysis.—The well-known agglutinating reactions of bacteria can be duplicated with red corpuscles. As with bacterial agglutinins the agglutinin seems to be, in Ehrlich's terms, a uniceptor; that is, it has but one group with affinity for other substances, as is the case with the toxins. Agglutinins for corpuscles are found to varying extent in normal serum, as well as in serums specifically immunized against the corpuscles. Heating at 55° C. does not destroy the agglutinin, and in this way the agglutination can be observed independently of the hæmolytic processes. Agglutination also occurs at temperatures approaching freezing, when hæmolysis is inhibited. Agglutinated red corpuscles collect in rouleaux and clumps that unite with considerable tenacity, so that ordinary shaking will not break them up. In hæmolytic immune serum this agglutination precedes the hæmolysis, but the two processes are quite unrelated. Normal serum may contain agglutinins and not be at all hæmolytic, and the converse is also true. The mechanism of agglutination is not understood, but it is suggested that some chemical change in the substance of the corpuscle renders the surface adhesive, or that some physical change in surface tension accounts for the coaptation and adhesion of the corpuscles. As agglutination occurs in corpuscles that have been fixed in formalin or sublimate, it is probably not the proteid of the corpuscle that is affected, but the other ingredients of the stroma, of which lecithins and cholesterin seem to be the chief. Flexner and Noguchi found that if ricin, an agglutinator, was allowed to act for two or more hours it is still possible then to produce hæmolysis by serpent venom, but the stroma remains at the bottom as a white, conglutinated mass. From this it appears that agglutination brings about a kind of coagulation of the stroma.

Agglutination of the corpuscles during life may be of some pathological importance, for such masses of agglutinated corpuscles could readily produce capillary thrombi and emboli, which, if widespread, might create much disturbance. Many bacteria produce substances that are agglutinative for human red corpuscles, among them being typhoid, pyocyaneus, and staphylococcus. Flexner has found in typhoid fever thrombi that seemed to be composed of agglutinated red corpuscles, almost free from fibrin and leucocytes. Probably many of the so-called "hyaline thrombi" found frequently in infectious diseases are really composed of agglutinated, partly hæmolyzed red corpuscles.

Agglutination is also produced by certain vegetable poisons, including ricin, abrin, and crotin, and these have been found to produce thrombi of agglutinated red corpuscles. Of these substances ricin alone, although strongly agglutinative, has no hæmolytic action, showing the independence of the two processes. Snake venom, like most hæmolytic substances, produces marked agglutination, and here also the agglutinin is distinct from the hæmolysin.

(3) HÆMOLYSIS BY BACTERIA.

Both pathogenic and non-pathogenic bacteria produce hæmolytic substances that are excreted into the fluids in which they grow. During many infectious diseases marked hæmolysis occurs, especially in those with septicæmia. After death the hæmoglobin of the blood goes into solution, and the resulting staining of the walls of the blood-vessels, and later of the tissues everywhere, is generally familiar. In the post-mortem hæmolysis probably the putrefactive organisms are chiefly concerned, although it is marked a very short time after death in many cases of septicæmia, particularly when the infecting organism is the streptococcus, and here probably the pathogenic organism is the chief cause of the hæmolysis. The hæmolytic action of bacteria can be studied both *in vitro* and *in vivo*. Among the best known are *tetanolysin*, *pyocyanolysin*, *typholysin*, *staphylolysin*, and *streptocolysin*, as they have been termed. Of these the case of pyocyanolysin is questionable because it has been described as resisting heat over the boiling point, and Jordan seems to have proved that the hæmolysis is ascribable to the alkalinity that this organism produces in culture media. Other bacterial hæmloysins are, however, destroyed by heat at 70° C. for two hours; that is, they are altogether different from ordinary cellular hæmolysins. G. Ruediger shows the following differences between streptocolysin and the hæmolysins of serum: Streptocolysin is not destroyed at 65° C. for one-half hour, and therefore is different from complement. When destroyed by heating to a higher point it cannot be reactivated by the addition of complement, thus differing from intermediary body. It is also different from intermediary body in that it does not combine with corpuscles at 0° C.; on the other hand it does combine at 6° C., but does not exert any hæmolytic effect until the mixture is raised to a higher temperature. This last observation indicates that the streptocolysin is similar in nature to the toxins, which exhibit the same phenomena. Other observations indicate that its structure is the same as the toxins, namely, a toxophore group and a haptophore group. In other words, streptocolysin is simply a toxin for red cells, which acts like bacterial toxins for other cells by joining directly to the cell receptors without the intervention of any intermediary body. As a similar structure has been shown for staphylolysin and tetanolysin, it is probable that the bacterial hæmolysins are all merely toxins with a particular affinity for red cells.

Secondary anæmia of the infectious diseases is probably to be explained largely by this hæmolytic property of bacterial toxins. Hæmoglobinuria also may be produced in the same way. Intravenous injections of filtrates of the saphrophyte, B. megatherium, will produce hæmoglobinuria in guinea-pigs.

(4) HÆMOLYSIS BY VEGETABLE POISONS.

A number of plant poisons are strongly hæmolytic; among them are phallin and helvillic acids from certain mushrooms; abrin, crotin, agaricin, saponin, solanin, and cyclamin. These hæmolytic poisons are not affected by heating at 100° C., and are therefore quite different from the serum hæmolysins. These substances are at present chiefly of interest from the laboratory standpoint, as being a distinct class of hæmolytic substances. Their mode of action is not clearly understood, but they seem to contain toxophore and haptophore groups like the true toxins.

(5) HÆMOLYSIS BY VENOMS.

The hæmolytic power of venom derived from different varieties of reptiles has through recent studies been brought into the domain of biologic hæmolysis, and the result has been not only an understanding of the mechanism by which the lethal effect of these poisons is produced, but also perhaps the strongest support of the principles of Ehrlich's theory yet offered from outside sources. At the same time a new, easily controlled medium for research in problems of immunity has been provided. The most fundamentally important fact is the discovery by Flexner and Noguchi that the hæmolytic and other toxic agents of venom are themselves true intermediary bodies. By itself venom is not hæmolytic, but it requires the presence of complement to enable it to produce hæmolysis, and as the venom contains no complement, this necessary part of the poison is furnished by the serum that contains the corpuscles. This is indeed a remarkable fact, that the active part of the serpent's poison is furnished by the victim itself, and particularly so in view of the position that serum complement usually assumes as a protector against bacteria. The existence of a widespread power against various animals implies that these venom intermediary bodies are capable of uniting with the complement of sera of varied animals, are *heterocomplementophilic*, in the language of Ehrlich's theory, and experiment shows this to be true. The probable source of these intermediary bodies is apparently in the serum of the serpents, as if they were secreted directly from the blood into the poison glands, for serum of poisonous snakes is found to possess intermediary bodies almost identical with those of the venom. The only difference is that while venom intermediary body combines with complement of nearly all serums, the serum immune body combines almost only with the complement of the serpent's serum itself (*isocomplementophilic*). Venom from cobra, rattlesnake, moccasin, and

opperhead possesses in each intermediary bodies that
eem to be identical in nature, although they may vary
n quantity. This explains the rather remarkable fact
hat serum of animals immunized against cobra poison,
enerally called *antivenin*, will neutralize the hæmolytic
nd many of the other properties of the venom of rattle-
nake, copperhead, and moccasin. Antivenin acts as an
nti-intermediary body, and by occupying one of its
ptophore groups prevents it completing the union of
mplement and cell. In order of decreasing hæmolytic
wer for mammalian corpuscles come venoms from
bra, water moccasin, copperhead, and rattlesnake.
ese venoms are also agglutinative for all corpuscles
ed, and agglutination will occur at 0° C. Exposure
thirty minutes at 75°–80° C. destroys the agglutina-
e property. In general, the hæmolytic power of the
oms for different sorts of corpuscles varies in inverse
portion to its agglutinative power. The hæmolytic
rmediary bodies are remarkably resistant to heat,
ering but slight loss of power at 100° C. Each
om contains many intermediary bodies, seemingly
rent for each sort of corpuscle hæmolyzed, at least to
eat part; no one sort of corpuscle can so saturate all
intermediary bodies that none is left for other kinds.
r the intermediary body is attached to a corpuscle
n unite with many different sorts of complements,
only the one natural to its serum accomplishes com-
hæmolysis. Leucocytes also are dissolved, and they
to have specific intermediary bodies different from
that unite with red corpuscles, but the agglutinin
ach seems to be the same. As the venom contains
amounts of intermediary bodies, when an animal is
ned by a snake the complement is quickly taken
nd this probably explains the deficient bactericidal
r of blood serum in this condition that permits the
sive infections so characteristic of snake bites.
enin will prevent this interference with normal
iolysis by occupying one of the groups of the inter-
ry bodies of the venom so that it cannot use up the
complement.

highly hæmolytic cobra venom can combine with
ments contained within the red corpuscles, *endo-
ment*, and so produce hæmolysis in the absence of
complement. Kyes has shown that *lecithin* may
constituent of the red corpsucles that acts as the
ment.

ssing it may be noted that the effects of venom on
nd endothelial cells, which with the hæmolysis
te the manifestations of its toxicity, are produced
same way as the hæmolysis. Amboceptors are
that unite complement to these cells, enabling it
k them. As certain venoms are richer in one sort
mediary body than others, so the effects of the
one kind of snake differ from those of another

sis in Disease.—During health there is always
certain amount of destruction of red corpus-
ve outlived their usefulness; so in disease we
deal with either an alteration in the normal
f blood destruction, or the introduction of entirely new processes. Although the place and manner of normal red corpuscle destruction is not completely known, yet it seems probable that there is relatively little hæmolysis within the circulating blood. When a red corpuscle becomes damaged it seems to become more susceptible to phagocytosis, and it is picked out of the blood chiefly by the endothelial cells of the sinuses of the spleen, hæmolymph glands, and bone marrow. Within these cells it apparently undergoes hæmolysis. Eventually the resulting pigment is split up by the liver, the non-ferruginous portion forming the bile pigments, while the iron seems to be mostly withheld to be worked over into new hæmoglobin. Whenever during disease red corpuscles are more rapidly injured than they are under normal conditions, these processes of normal hæmolysis are exaggerated and we not only find the phagocytic cells of the spleen and glands packed with them, but endothelial cells elsewhere and leucocytes also take on the hæmolytic function. At the same time there is an excessive production of bile pigment from the destroyed red corpuscles, which has an undetermined relation to the so-called ' hæmato-hepatogenous " jaundice. If hæmolysis is very excessive the blood pigment accumulates in other organs than the liver and spleen. When at one time over one-sixtieth part of the hæmoglobin of the blood is in solution in the plasma, it may escape in the urine, producing hæmoglobinuria.

The hæmolysis of the acute febrile diseases is readily explained by the demonstrable hæmolytic property of the products of the organisms that cause them, such as streptocolysin, staphylolysin, etc. Perhaps at the same time altered metabolic products may also play a part, but it does not seem probable from experimental results that the thermic condition *per se* has much effect. In malaria, although the parasites enter and destroy the corpuscles in which they live, yet this alone does not account for all the blood destruction of the disease, for the amount of anæmia is quite without relation to the number of parasites to be found. There is good reason to believe that the plasmodia produce hæmolytic substances that are discharged into the serum. In the primary anæmias hæmolysis seems to be the essential process, although the agents involved are at present unknown. Absorption of hæmolytic products of intestinal putrefaction or infection has always come in for much suspicion, without ever becoming completely established. Here also the hæmolysis seems to take place in the endothelial cells rather than in the vessels. In such a disease as pernicious anæmia there is much reason to assume that defective or abnormal hæmatogenesis is an important factor. Probably the anæmia of nephritis is the result of hæmolytic action of the retained products of metabolism, in which connection the hæmolytic properties of ammonium compounds may be recalled. In some diseases associated with anæmia it has been found that the blood serum of the patient is distinctly isohæmolytic, although isoagglutination seems to be more frequent. Such sera, however, do not seem to be autohæmolytic, at least in the test tube. The bloody fluids that can be obtained from cancers have been found to be hæmolytic, while antihæmolysin has been found in ascitic and pleural effusions.

In many forms of poisoning hæmolysis is a prominent feature; in some it seems to be the chief effect of the poison, *e.g.*, potassium chlorate and arseniuretted hydrogen. In severe extensive burns there may occur hæmolysis, and hæmoglobinuria may also result. The remarkable "paroxysmal hæmoglobinuria" is at present without satisfactory explanation as to the cause of the hæmolysis. The hæmoglobinæmia of "blackwater fever" has been the cause of much discussion as to whether the malarial parasite or the quinine is the cause, with a divided opinion resulting, although undoubtedly cases do occur in malaria without administration of quinine. After removal of the spleen hæmolysis by the hæmolymph glands exceeds that of the primitive spleen, causing an excessive destruction of red corpuscles (Warthin). This suggests that the spleen may normally dispose of some hæmolytic agent which acts either by stimulating phagocytosis or by so altering the red cells that they are particularly susceptible to phagocytosis.

The lesions produced in the organs of animals injected with hæmolytic agents are usually pronounced and quite characteristic. There is often a subcutaneous œdema, frequently blood-stained, and similar fluid may be present in the serous cavities. The fat is yellowish, and the muscles are darker in color than is normal. The spleen is usually much swollen, soft, friable, and very dark in color. The liver is usually swollen and mottled with red areas in a yellow background. The renal cortex is dark in color, even chocolate-colored, and the pyramids are comparatively light; in the urine is frequently hæmoglobin. In the lungs are often hemorrhages or areas resembling small infarcts. The blood may be thin and even distinctly transparent. Microscopically the red corpuscles are found in all conditions of degeneration, and often fused together. In the liver, besides patches of congestion, fatty changes are present if the animal lives long enough. Large phagocytic cells packed with red corpuscles are abundant in the spleen, as well as diffuse accumulations of blood, often fused, and pigment both free and in the cells. Pigment also accumulates in the renal epithelium, which also often shows much disintegration; congestion is prominent and hemorrhages into both interstitial tissue and glomerules are frequent.

BACTERIOLYSIS.—It is not our purpose in this article to discuss the specific micro-organisms in this relation, but merely to indicate the relations of hæmolysis and bacteriolysis. Whatever has been said in preceding paragraphs about the mechanism of hæmolysis can be transcribed to apply to bacteria and bacteria-immune serum. Pfeiffer's observation of the solution of bacteria by serum of immunized animals was the precursor of the modern studies of hæmolysis and the extension of Ehrlich's theory. Indeed the chief reason for the great interest in hæmolysis lies in the understanding that whatever may be learned about hæmolytic processes can be directly applied to the processes of immunity against bacteria. Therefore we understand that in the serum of an animal immunized against bacteria themselves, and not merely their toxins, there is present an intermediary body that is specific for the injected organism. This intermediary body attaches itself to the bacterium by one haptophore group, and with the other anchors the complement of the serum which then destroys the bacterium. Now as during immunization only intermediary bodies are produced in excess, while the complement is not increased, it often may be that defence may fail because of deficiency in the amount of complement. This possibly explains why it has so far been impossible to secure immune sera that will protect against bacteria as effectively as antitoxin protects against toxin, for with toxin no complement is required. The results of decreased complement content would be an increased susceptibility to infection, and this is seen in snake bites, when the venom uses up the blood complement and the patient often succumbs to bacterial infection after surviving the direct effects of the poison. In chronic diseases Longcope claims that in the later stages the amount of complement is much decreased, probably accounting for the occurrence of terminal septicæmias.

It is probable that hæmolytic complement is quite distinct from that causing bacteriolysis, and that complements for different bacteria can be separated from one another as well as from the agglutinins.

Welch has suggested that possibly the bacteria in their turn may develop antibodies to the tissues and fluids in which they are growing. If so, we have a reasonable explanation of the development of toxic substances with marked action on specific cells of the host, *e.g.*, endotheliolysins, leucolysins, hæmolysins; and also the peculiar manner in which bacteria often attack only certain tissues, *e.g.*, multiple septic arthritis.

CYTOLYSIS.—Red corpuscles being merely a particular sort of body cell it might be expected that lysins for other cells could be obtained in a similar manner, and such is the case. Such lysins are called by the generic term *cytolysins*, or *cytotoxins*, and are specifically indicated by the name of the cell concerned, as endotheliotoxins or endotheliolysins, hepatotoxins, nephrotoxins, etc. The lysins or toxins in this case are similar in composition to the hæmolysins, that is, an amboceptor and a complement group, and these groups are in all respects similar to the components of the hæmolysins except that the cytophile group of the amboceptor is specific for certain tissue cells rather than for red corpuscles. Such specific cellular toxins may be obtained by immunizing the animals against the tissue which is injected emulsionized into its peritoneal cavity; but, as with the hæmolysins, they may occasionally appear in normal serums of various sorts of animals. It is by no means as easy to determine the results with tissue cells as with red corpuscles, where the liberation of the highly colored hæmoglobin is easily detected. To some degree lytic changes can be observed in tissue cells under the microscope, but this is not usually very satisfactory. Another method of observation consists in injecting the immune serum into the body of an animal, and studying both the symptoms and the anatomic changes brought about in this way. The latter method has found the most general application. A disturbing element in all such experiments lies in the difficulty of securing tissue cells of one kind alone for injecting. For example, when hepatic-tissue suspensions are injected there are introduced at the same time endothelial cells, connective-tissue cells, and usually red corpuscles and leucocytes. Therefore an immune serum obtained in this way would contain immune bodies for all these cells, and it becomes impossible to ascribe any changes that follow its injection into an animal solely to effects of the hepatotoxins. While there are possible ways of avoiding many of these difficulties they have not been generally applied, and much of the earlier work is very questionable on this account. At the same time that cytolysins are formed agglutinins also appear, and agglutination of specific cells occurs as it does with bacteria and corpuscles. One of the earliest pieces of work in this direction was with sperm agglutinins, obtained by immunizing with sperm. Such serum, however, was not spermolytic. In view of the elementary condition of cytolytic investigations, and the afore-mentioned sources of error in much of the work that has already been reported, I do not feel justified in this article in more than briefly discussing the specific results so far obtained. It should also be mentioned that recently some investigators who have used care in avoiding hæmolysins, etc., in preparing specific sera have not been able to obtain as marked results as had been earlier reported.

Leucocytolytic Serum.—This may be obtained either by immunizing with leucocytes obtained from exudates or from the blood, or by using emulsions of lymph glands. The latter method introduces so many cells besides the lymphocytes that it is not desirable. Specific leucocytolytic sera agglutinate leucocytes and produce observable morphologic changes, in the way of solution of the cytoplasm and cessation of amœboid movements. Of the leucocytes the large granular cells seem most affected and the lymphocytes least. When injected into the peritoneal cavity such serum causes an apparent initial leucopenia, and later a decided leucocytosis in the peritoneal fluid. Corresponding with this, if bacteria are injected at the same time as the serum, resistance is found decreased, but later it is much increased. Such serum also contains anticomplement, according to Wassermann, indicating that the injected leucocytes contain complement. Leucotoxin obtained by immunizing against lymphatic tissue is very thermolabile, being destroyed by 55° C. for thirty minutes, and the serum can be only partially reactivated by the use of fresh serum. Undoubtedly leucotoxic amboceptors are present in many normal sera, and their presence in the serum of certain cold-blooded animals and in venom has already been shown.

Endotheliolytic Serum.—Every attempt at immunizing an animal with any sort of fixed tissue must of necessity

lve the injection of endothelial cells as well as those
ific to the tissue studied. Therefore it is possible
cytotoxic serum so obtained will contain endothelial
ıs and so complicate any results of *intra vitam* experi-
s. There is every reason to believe that endothe-
ic substances are produced in this way. Ricketts
l that serum of animals immunized against lymph
ls was toxic to endothelial cells, which was indi-
by hemorrhages at the point of injection, and
ed desquamation of endothelium when the injection
nade into a serous cavity. In snake poisoning the
sive hemorrhages are also due to an endotheliolytic
iple, called by Flexner *hæmorrhagin*. This is de-
ed by heating at 75° C., and is particularly abun-
in fact, the chief toxic agent in rattlesnake venom.

nphatolytic Serum.—This serum has been studied
ly by Ricketts and by Flexner, immunizing ani-
with lymph glands. As might be expected from
ature of the injected glands the resulting serum
ned endotheliotoxin, leucotoxin, hæmolysin, hæma-
in, leuco-agglutinin, and precipitins. When in-
into animals this serum had a marked effect upon
leen and lymph glands, producing great enlarge-
of these structures, which were also congested.
ne marrow was also somewhat affected, and when
w was used in immunizing, the *myelotoxic* serum
ed marked proliferative changes in the lymph
as well as in the marrow. The changes produced
leucocytes were the same as those described for
xic serum, indicating that the different forms of
tes can combine with immune bodies produced
lymphocytes.

rolytic Serum.—It has been claimed that if a kid-
destroyed by ligating its vessels or ureter the re-
g kidney develops serious degenerative changes,
are not present if one kidney is entirely removed.
s been attributed to the development of nephro-
ubstances produced in reaction to the absorption
njured renal tissue that has been left in the body.
methods of renal injury have been thought to
similar effects, and serum of animals with kid-
ease was said to injure the kidneys of normal
. From this basis it has been thought to explain
gressive nature of the chronic nephritides as the
f nephrotoxins produced through the absorption
njured cells, and which nephrotoxins injure still
lls. Such a process, however, involves the pro-
of cell toxins in an animal toxic for its own cells,
utocytotoxins; and as it has so far been practically
le to produce autolysins of other sorts, it is not
er probable that the kidney is an exception.
nore, the latest writer, Pearce, was unable to pro-
ephrotoxins, and could not corroborate the results
have been found in the remaining kidney after
the vessels of the other. He did obtain an ac-
onephrolysin, but also found that immunization
r produced just as actively nephrolytic serum
nization with kidney.

ytic Serum.—Even so highly specialized cells as
the nervous tissue seem to produce a reaction
formation of immune bodies. Perhaps because
ptoms produced by action on the nervous sys-
o readily detected, and because of the advanced
of our knowledge concerning the minute struct-
anglion cells, the results obtained with neuro-
m have been particularly striking. Perhaps
positive results are those of Ricketts and Roth-
o found that serum of rabbits immunized
e brains or cords of guinea-pigs, when injected
essels of guinea-pigs was highly toxic, causing
th various symptoms only explainable on the
n of nervous lesions. Microscopically the
cells showed marked changes in those animals
ived the injection long enough. All the results
tained have been with heterogeneous serum.
particularly that of cobra, possess strong neu-
bstances, that are the chief toxic agents in most
noms (the rattlesnake excepted). This neurolysin can be removed by saturation with nervous tissue from the hæmolysin, and conversely the hæmolysin can be removed by saturating with red corpuscles, thus corroborating Wassermann's experiments with tetanus toxin and supporting Ehrlich's theory.

Thyrolytic Serum.—There are but few reports on this serum, but of these the latest, that of Portis, indicates that after removal of all hæmolysis as a factor there do occur changes in the nature of excessive absorption of colloid, and proliferation after the order of that seen in regeneration. However, the clinical picture of thyroidectomy was not produced in any case, and the anatomic changes were not great.

Numerous reports may be found indicating attempts with varying success to obtain sera toxic for other tissues. Among them may be mentioned *epitheliolysin* (for ciliated epithelium), *spermatotoxin*, *hepatolysin*, *cardiolysin*, *splenolysin*, and *syncytiolysin*. Attempts at the production of immune serum with adrenal by Abbott resulted only in a serum with great hæmolytic power, but with no particular effect on the adrenal. The principle in all is the same, but the results as a whole are not now in a state to warrant extensive consideration. In general, it can be said that it has not been found possible in this way to throw out of function one particular organ, with or without involvement of other structures. It must be borne in mind that we can have grave functional disturbances without corresponding anatomic alterations. There is no reason known why a group of receptors of essential importance to the functional manifestations of the cell may not be quite independent of vegetative functions; and with impairment of these alone there need be no visible cell changes. *H. Gideon Wells.*

BIBLIOGRAPHY.

Excellent reviews bearing upon these topics, to which the reader is referred for the bibliography of the earlier works, are found in: "A Review of Current Theories Regarding Immunity," by James Ritchie, Journal of Hygiene, 1902, ii.; Ehrlich's "Croonian Lecture," in the Proceedings of the Royal Society of London, 1900, lxvi.; and in the book by Vaughan and Novy, "Cellular Toxins," 1902.

References to all the later literature of importance will be found in the reviews of pathologic literature by Hektoen, in Progressive Medicine, each year since 1900.

HEMLOCK, POISONING BY.—The water hemlock (*Conium maculatum*) is a small herb, belonging to the natural order *Umbelliferæ*. It must not be confounded with the hemlock tree (hemlock spruce), a well-known product of the forest regions of the United States. Conium maculatum is indigenous in Europe, but has established itself to a limited extent in other countries. It is regarded as the poison which was used by the ancient Athenians in putting to death certain criminals, and has become famous in consequence of its use in the case of Socrates.

The poisonous properties exhibited by several parts of the plant, especially the fruit, are due to several alkaloids, of which conine (sometimes called coniin) is the most important. This is a distinct alkaloid, forming a series of salts, and is one of the few of its class that are liquid at common temperature and do not contain oxygen. Its formula is $C_8H_{17}N$. It is a colorless liquid, specific gravity about 0.880, not very soluble in water. It boils at a temperature considerably above that of water, and has a distinct rotatory action on polarized light. Its odor is usually said to be mouse-like, a rather vague description, but it cannot be more directly described, except to say that it is strong and disagreeable.

Cases of hemlock poisoning have been mostly accidental, parts of the plant having been mistaken for edible herbs, such as parsley. The recorded cases give diverse symptoms, and it is highly probable that mistakes have been made as to the identity of the plants in several instances. The following summary represents the marked features: Headache, vertigo, dilated pupils, a prickling sensation in the extremities, with gradually developing paralysis. This latter usually begins in the legs. The paralytic condition extends to the muscles of the trunk and neck, speech and deglutition become imperfect, and finally asphyxiation may occur by failure of the respiratory muscles. The mind is not much impaired until the latest stages of the case. Convulsions may occur at an advanced stage. A case may last several hours, but is likely to be much more rapid in its progress, death sometimes occurring in a few minutes. The poisonous dose is small, but cannot be accurately fixed from the data at hand. Probably one drop of coniïne would be fatal to an adult in most instances if treatment was not promptly instituted.

Treatment must be of the type used for the alkaloids in general. Tannin and animal charcoal have some antidotal value, but the thorough washing out of the stomach will be found to be of most advantage and should be instituted as soon as possible. Artificial respiration may be required in the advanced stages of the case. The marked paralytic condition suggests the use of strychnine in very small doses hypodermically, but such treatment must be used with caution.

The detection of the characteristic alkaloid is a difficult matter, but its peculiar odor will be of value. More important, from a practical medical point of view, is the recognition of parts of the plant. These should be carefully examined, and compared with authentic specimens, or mistakes will be made, for species of Umbelliferæ are often difficult to differentiate. The post-mortem appearances are not characteristic. *Henry Leffmann.*

HUNYADI JANOS SPRING, AUSTRIA.—A mineral spring at Ofen, Hungary, a part of Budapest. The water bearing this name, so universally used, especially in this country, is one of the "Hungarian bitter waters"; others, almost as well known and obtained from the same locality, are the Franz-Josef and the Apenta. These three are the strongest of the bitter mineral waters, and are used either as a laxative or as a cathartic, the effects depending upon the quantity of the water taken. The active ingredients are the sulphates of sodium and magnesium. The following table shows the proportions in which they occur in the various Hungarian waters; and, for purposes of comparison, several other waters of like constituency are included.

ONE LITRE OF WATER CONTAINS:

	Sodium sulphate. Grams.	Magnesium sulphate. Grams.
Hunyadi Janos	22.55	22.35
Franz-Josef	23.18	24.78
Apenta	15.40	24.40
Puelina	9.59	10.85
Friedrichshall	6.05	5.15
Kissingen Bitterquelle	5.80	5.00

The following is an analysis of the Hunyadi Janos water by Professor Bunsen. One pint contains: Sodium carbonate, gr. 13.20; ferrous (oxide) carbonate, gr. 0.08; calcium carbonate, gr. 6.04; strontium carbonate, gr. 0.19; sodium chloride, gr. 11.54; potassium sulphate, gr. 1.67; sodium sulphate, gr. 128.97; magnesium sulphate, gr. 187.98; silicious earth, gr. 0.09. Total, 299.76 grains. Free and partly combined carbonic acid, 8.06 cubic inches.

Other well-known waters of like character are those of the Rubinat Condal, Rubinat Serre, and Rubinat Llorach Springs in Spain.

The taste of these waters is disagreeably bitter, much like a solution of "Epsom salts," although it is said to be somewhat modified by the presence of free carbonic acid and the other salts; at best, however, they are not a pleasant drink.

These sulphated bitter waters are much employed either as an occasional aperient, or in habitual constipation and in dyspepsia accompanied by constipation. They are also a serviceable laxative in small doses in pregnancy, arteriosclerosis, cardiac disease, and other morbid conditions in which an unstimulating laxative is desired. In large doses they are indicated where a rapid, full evacuation of the bowels is the end in view. In brief, in all the innumerable conditions in which a "dose of salts" is indicated, these bitter waters, which are practically a solution of salts, can be used. The usual dose of the strong bitter waters is from a half to one wineglassful taken on an empty stomach. In emergency cases a larger dose can be taken—from three-quarters to one tumberful.
Edward O. Otis.

IRON, POISONING BY.—Metallic iron and those compounds of iron which are insoluble in water are not poisons. The soluble salts, however, though not active poisons, have an irritant action, and are capable of destroying life when taken in large doses and in a concentrated state. The continued administration of medicinal doses even produces, after a time, decided gastric disturbance. It is probable that all the soluble preparations may act as irritant poisons when administered in large doses. The most important, however, from a medicolegal point of view, are ferrous sulphate (copperas, green vitriol), ferric chloride (perchloride), which is used medicinally in the form of tincture, and the tannate in the form of ink.

The salts of iron are rarely administered for criminal purposes. Most of the reported cases of poisoning have been the result of accident, or of the use of the sulphate or the tincture of the chloride of iron in attempts at abortion. The symptoms which follow the administration of large doses of the preparations named are essentially similar to those produced by the irritants in general. There are a styptic taste in the mouth, nausea, vomiting, pain in the stomach and intestines, and purging. The evacuations are black, owing to the conversion of the iron salt into a tannate by the tannic acid of the food, or into a sulphide by the sulphureted hydrogen resulting from decomposition in the intestines. Irritation of the genito-urinary passages is sometimes observed. The tincture of the chloride of iron is more corrosive in its action than the sulphate, by reason, apparently, of the free hydrochloric acid which it frequently contains. Its injection into the cavities of the body, for the purpose of arresting hemorrhage, has proved fatal.

The amount of any of the preparations of iron required to endanger life is not accurately known, but appears to be quite large. In most of the cases in which the sulphate has been taken, the amount was unknown. Recovery has taken place after a dose of 31 gm. (℥ i.) of the sulphate (Christison). A case is reported in which 48 gm. (fl ℥ iss.) of the tincture of the chloride of iron proved fatal in about five weeks (Christison). Recovery has taken place after doses of 32–96 gm. of this preparation. The favorable issue is probably due, in many cases, to the early occurrence of vomiting.

The results of experiments on animals are not uniform. Gmelin states that 7.7 gm. (ʒ ij.) of the sulphate of iron administered to dogs by the mouth caused vomiting only; that 2.6 gm. (gr. xl.) administered to rabbits produced no injury; and that 1.3 gm. (gr. xx.) injected into the veins of a dog produced no symptom whatever. Dr. Smith, however, states that 7.7 gm. will prove fatal to dogs when administered by the mouth or applied to a wound.

The post-mortem appearances are those of a simple irritant, and are confined, so far as has been observed, to the stomach and upper part of the intestines. In acute cases the contents of the intestines will probably present a black appearance, owing to the presence of the tannate or the sulphide of iron.

Iron is eliminated to some extent in the urine. A small amount only is absorbed in any event, the greater part escaping in an insoluble form with the fæces.

Treatment consists in the use of the stomach-pump, or of emetics if necessary. Magnesia or dilute solutions of alkaline carbonates should be administered as antidotes, and these should be followed by demulcents.
William B. Hills.

LIPOMA (Adipoma, Steatoma) is a tumor consisting essentially of adipose tissue. Such growths belong to the mature connective-tissue tumors, and have for their physiological prototype the adipose tissue found beneath the skin and serous membranes. Between normal adipose tissue and the fat tissue of lipomata there are no essential differences of structure. In the majority of lipomata the fat cells as well as the fat lobules are usually larger than those of normal adipose tissue (the former three to four times as large); but this difference does not hold good to such an extent that it can be used as a point in differential diagnosis. In general, a lipoma presents the structural characteristics of a localized mass of fat differing in no respect from normal subcutaneous fat. The chemical reactions of the fat contained in lipomata likewise correspond to those of normal fat.

Since the resemblance in structure to normal adipose tissue is so very close, it may sometimes be difficult to draw a line between a simple hypertrophy of adipose tissue and a lipoma. Both general and local hyperplasias of adipose tissue occur which are not classed with lipomata (general lipomatosis, lipomatous elephantiasis, the deposit of fat about an atrophic kidney or between the bundles of atrophic muscles); but other local hyperplasias of a similar nature have by various authors been styled lipomata. Thus the hyperplasia of the fatty capsule of the mammary gland which occurs sometimes in scirrhous carcinoma of this organ or in chronic interstitial mastitis has been called *lipoma capsulare*, an excessive deposit of fat beneath the epicardium has been styled *lipoma cordis capsulare*, and the deposit of fat in the villous fringes of the joints is known as *lipoma arborescens*, although analogous to the fatty hyperplasia so frequently seen in the epiploic appendages of the large intestine. Such local fatty hyperplasias may be styled *pseudolipomata*. An exact use of the term lipoma would limit its application to those formations of adipose tissue alone in which an actual new formation of fat tissue occurs. Such a criterion has, however, but little practical value, since in the fully developed growth of fat tissue it may be impossible to say whether the latter has arisen from a circumscribed hyperplasia or represents a true neoplasia. This difficulty is increased by the fact that lipomata are usually found in those parts of the body in which there is normally more or less fat tissue. A more practical guide will therefore be found in the principle that the term lipoma should be applied to *circumscribed proliferations of adipose tissue which show a certain anatomical and physiological independence of the neighboring tissue, even when the latter is fat tissue.*

The application of the term lipoma made by some writers to tumors other than connective tissue, the cells of which have undergone fatty degeneration or contain an abundance of fat, is wholly incorrect. The true lipomata belong to the mature connective-tissue tumors—that is, the tissue of which they are composed is of the type of adipose tissue.

HISTOGENESIS.—The histogenesis of lipomata is not yet definitely known. Their very frequent development in regions where fat tissue is normally found has led to the belief that the majority arise from a hyperplastic proliferation of adipose tissue with new formation of fat cells and fat lobules. Such an explanation would hold good even for the lipomata which are sometimes found in the submucosa of the gastro-intestinal tract, since in well-nourished individuals fat cells are usually present in small numbers in this region, and from these a lipoma could take its origin. Another view is that lipomata arise from undifferentiated embryonal cells which have persisted from fœtal life, or are formed by the proliferation of connective-tissue cells. The development of fat tissue from these follows the same course as that of the normal development of fat cells from fœtal myxomatous tissue. It is not improbable that undifferentiated "primitive fat organs" (developing fat lobules in the fœtal mesenchyma) may persist quiescent until adult life and later resume active proliferation, giving rise to localized growths of fat tissue which in their development would be more or less independent of the normal laws of nutrition and cell growth. Support is given to this theory by the fact that some lipomata in their growth appear to be entirely independent of the laws governing the general nutrition of the body, since they continue to increase in size or at least do not become smaller under conditions of cachexia, etc., when the normal fat tissue is being reduced in amount. The fact that a combination of myxomatous tissue and adipose tissue is frequently found under pathological conditions may also be taken as an indication of the close histogenetic relations of these tissues. In many lipomata areas of myxomatous tissue occur, and occasionally the appearances presented suggest the development of the fat tissue out of the myxomatous. Moreover, there are rare forms of lipomata in which the fat cells resemble those of embryonic adipose tissue, in that the fat droplets are of small size and do not coalesce into larger drops filling the entire cell.

A further origin for lipomata may be found in atrophic lymphadenoid tissue, a physiological paradigm being found in the development of fatty marrow from the lymphoid marrow, and the fatty transformation of the thymus, and later in old age that of the lymphatic glands. The relationship between lymphoid tissue and adipose tissue is very close. In the fœtus the development of the lymph glands is either coincident with that of the primitive fat organs or follows it; in the latter case the lymphadenoid structures (both ordinary lymphatic and hæmolymph nodes) developing out of the fat organs. In adult life under certain conditions a new formation of lymph glands takes place from adipose tissue, and in old age the lymph glands become to a large extent replaced by fat tissue. Throughout life it is very probable that there is a constant cycle of alternation between lymphoid tissue and adipose tissue. As the result of some disturbance of these processes it is possible that lipomata may arise, either from atrophic lymph glands or from anlage of undifferentiated cells. Askanazy traces the origin of multiple lipomata in particular to a replacement of lymph glands by fatty tissue.

The lipomata of the uterus, kidney-cortex, brain, spinal cord, etc., are to be referred to misplacements of anlage of fat tissue or of fibrous connective tissue which later undergoes a fatty metaplasia. Such lipomata are to be classed with the heterotopous teratomata. It should be borne in mind also that lipomatous masses not infrequently form the bulk of teratomata found in other regions as well.

ETIOLOGY.—As in the case of the other true neoplasms but little is known of the etiology of lipomata. Some of them may arise as the results of trauma or chronic inflammation. Such an origin has been ascribed to the fatty tumors sometimes found in the hands of working people in the parts most exposed to injury. In other cases fatty tumors have been found developing from scars. The fatty growths in the villi of the joints are usually associated with a chronic arthritis. There also seems to be some association between multiple lipomata and rheumatoid affections. In the case of the multiple and symmetrical lipomata a nervous or trophic origin is assumed by many writers. In such cases other symptoms suggesting a neuropathic origin are not infrequently present. According to Grosch, multiple lipomata of the skin arise from a disturbance of fat secretion by the skin glands due to a trophoneurosis. A connection between lipomata and disease of the thyroid and hypophysis has also been assumed by some authors. In the majority of cases it is very probable that lipomata are to be regarded as congenital, that is, they arise from misplaced anlage. A tendency to the development of lipomata appears also to be inherited in some families.

Gross Appearances.—All lipomata possess a more or less definite capsule. In the sharply circumscribed forms the capsule may be well defined, of varying thickness; in the diffuse forms the capsule is not perfect and often sends prolongations of connective tissue into the surrounding tissues, which if not removed may lead to a recurrence of the growth. The size of lipomata varies greatly; in the kidney, submucosa of the intestinal tract, etc., they may be very small, while in the subcutaneous tissues of the shoulder and back and in the retroperitoneal tissues they may give rise to tumors weighing fifty pounds or more. As a rule, they do not exceed ten pounds in weight. They usually form lobulated growths of more or less regular contour. A subdivision of the larger lobules into smaller ones gives the growth a tuberous appearance. Lipomata are not infrequently pedunculated, particularly those found in the submucosa of the alimentary tract, though even in the skin the tumor may occasionally possess a relatively long and narrow pedicle (*lipoma pendulum*). Accessory nodules are rarely seen about the main growth. In the majority of cases lipomata are solitary. Occasionally they are multiple, and in such cases the tumors may be symmetrically distributed over the body. As a rule, lipomata are soft, elastic, and may give a sensation of fluctuation. Puncture with a trocar yields no fluid except in those cases in which extensive retrograde changes have taken place. The absence of fluid on aspiration may therefore have a certain diagnostic value. The occurrence of retrograde changes may render the growth either harder or softer. As a rule, the cut section of a lipoma presents a yellowish or whitish, glistening, lobulated surface, having the characteristic appearances of adipose tissue. In the majority of cases the microscopical examination is hardly necessary for the diagnosis.

Microscopical Appearances.—As stated above, the minute structure of lipomata corresponds in general with that of normal subcutaneous fat. Other varieties of tissue may take part in the make-up of the growth. If the fibrous trabeculæ are developed to such an extent that they form a prominent feature of the tumor the latter may be styled a *fibrolipoma*. As the result of the increased consistence of such tumors they are also called *lipoma durum* or *steatoma*. A combination of myxomatous tissue with fatty tissue gives rise to a *myxolipoma*. *Osteolipomata*, *chondrolipomata*, and *myolipomata* have also been described. An abundant blood supply with over-development and dilatation of the blood-vessels gives rise to the form known as *teleangiectatic lipoma*; the formation of blood spaces resembling those of erectile tissue to the variety known as *lipoma cavernosum*. The soft form of fibroma may also be combined with a lipoma. To very cellular varieties of a sarcomatous nature the term *liposarcoma* may be applied. Such forms are rare, sarcoma developing less frequently in lipoma than in any other benign connective-tissue tumor. In rare cases an excessive formation of fat of lipomatous nature may be combined with sarcoma or carcinoma. Lipomatous formations are not uncommon in teratomata, and may form the bulk of the tumor. The presence of other histological elements such as epithelial and nervous tissues gives a basis for differential diagnosis. Varieties of lipomata have also been described in which the fat tissue presented the appearances of embryonic adipose tissue.

Evidences of the growth of the lipoma may be found either in the capsule or in centres of growth which are scattered throughout the tumor. The new formation of adipose tissue may therefore take place peripherally or at different places in the tumor. A fibrous connective tissue is usually first formed, and this later undergoes metaplasia into fat tissue.

Manner of Growth.—According to their manner of development lipomata may be classed as *solitary*, *multiple*, *circumscribed*, *diffuse*, *symmetrical*, etc. The diffuse and multiple forms are closely related on the one hand to the simple hyperplasias of fatty tissue resulting from anomalies of metabolism, overeating, etc.; and, upon the other hand, to the multiple fibromata, chondromata, osteomata, etc., which are congenital or develop from misplaced anlage.

The *diffuse* and *multiple* lipomata, particularly the *symmetrical* forms, have in recent years attracted much attention, and various hypotheses have been advanced in explanation of their origin. In certain cases there appears to be some definite connection between disturbances of the nervous system and the development of multiple lipomata. Numerous clinical observations show the coincidence of occurrence of multiple lipomata and nervous conditions. The development of symmetrical lipomata in association with disturbances of sensation and motion has been seen in the lower extremities after injury to the spinal column. Neuralgias, trophic disturbances of the skin, etc., have been observed in connection with multiple and symmetrical lipomata. It is probable of course that in some of these cases the nervous disturbances may be the result of pressure by the tumor. Lipomata which are themselves painful are also seen. In such tumors there may be a new formation of nerve fibres, or the tumor may spring from the connective-tissue sheaths of the nerve trunks or the symptoms may be the result of pressure. An exact anatomical distribution of the tumors to accord with the peripheral nerves cannot always be made out. Multiple lipomata may also be inherited. Blaschko reports the case of a family in which the male members developed multiple lipomata at the age of puberty, while the females were not affected. The coincidence of multiple lipomata with rheumatoid affections has already been mentioned.

Broca has reported an extraordinary case of multiple lipomata. In a man of the age of twenty-five years there appeared on the right thigh a small fatty tumor which in six years attained a large size. It was excised, found to weigh five pounds, and to consist of ordinary adipose tissue. The patient remained well for five months when there occurred an eruption of hundreds of small fatty tumors all over the body, fresh ones developing from time to time during a period of forty years. At the age of seventy the man came under Broca's care for treatment for dysphagia. Two thousand and eighty tumors in size from that of a pea to that of a walnut were counted over the body, more minute ones not being included. The original scar showed no signs of disease. The microscopical examination of portions of the growths removed during life gave the appearance of lipofibroma. Increase of dysphagia caused emaciation to set in. This at first did not affect the tumors, but after several weeks the emaciation became extreme and the tumors diminished. The patient finally died of starvation. At autopsy no trace of fat was found in the normal fat depots. A large fatty tumor surrounded the œsophagus for the greater part of its extent, occluding the lumen; the pylorus was surrounded by a similar growth. Fatty growths were found in the valves of the heart, in the deep tissues of the neck, in the sheath of the carotid vessels, and in the sheaths of the muscles, as well as in the normal fat regions. Many of the tumors had lost their fat, they consisted of fibrous tissue; the others presented the appearances of fibrolipomata. It is difficult to explain such a case as this except on the ground of a congenital anomaly.

Site.—Lipomata are found most frequently in those parts of the body where fat tissue is most abundant normally: in the subcutaneous, subserous, and submucous fat, and the intermuscular connective tissue, and less frequently in the kidney, periosteum, joints, tendon sheaths, meninges, etc.

Subcutaneous.—Circumscribed lipomata are found more frequently in the subcutaneous tissues than elsewhere, appearing as movable, lobulated, elastic tumors. The neck, back, gluteal region, thighs, axillæ, anterior abdominal wall, arms, hands, and feet are mentioned in the order of frequency of involvement. Lipomata of the scalp and face are rare. The palms of the hands are more often the seat of fatty tumors than the soles of the feet. In the hands lobules of fat may extend from the main mass of the tumor underneath the palmar fascia. Small lipomata may be found occasionally on the fingers. In regions where the skin is loose the lipoma may become pedunculated. Subcutaneous fatty tumors may reach a very large size. They are sometimes painful and may be associated with nervous symptoms. Ordinarily they are painless. Over the large ones the skin may be stretched to such an extent that it may become very atrophic or may undergo ulceration. In this way the tumor itself may become infected. The loose nature of the fatty tissue and the low resistance of the surrounding tissue make such an infection dangerous, as it is very likely to become phlegmonous.

The diffuse pseudolipoma of the subcutaneous tissue of the neck may be mentioned here. It is in reality a diffuse fatty hyperplasia and gives rise to the condition known as "fatty collar." The deeper fascia may also be involved, and the lipomatosis may spread over the back, shoulder, and trunk. Similar fatty hyperplasias may occur in the subcutaneous tissue in other parts of the body. In some cases they are symmetrically arranged. In the majority of these cases there seems to be a definite connection between the condition and chronic alcoholism. Under changed conditions the fatty deposits become smaller. The diffuse, multiple, and symmetrical fatty deposits are therefore better classed as pseudolipomata.

Subserous.—Small lipomata are not rare in the subserous tissues. Polypoid fatty growths are occasionally seen in the peritoneum, pericardium, pleura, and the synovial membranes. When possessing a definite pedicle the latter may become twisted and atrophy, or may tear, setting the tumor free into the serous cavity where it appears as a free mass of fat showing more or less calcification. The subserous lipomata may reach a large size, particularly in the retroperitoneal region, and may become dangerous through the pressure exerted upon important organs. Adami has discussed at length the subject of retroperitoneal lipoma, collecting forty cases from the literature and reporting several of his own. As a rule, the fatty tumors of this region are slowly growing, but may attain a very large size. They are usually situated more to one side than to the other, and are usually crossed by some portion of the large intestine. Since they give fluctuation they are generally at first mistaken for cystic tumors, but puncture with the trocar yields no fluid. This fact is the most important point in the differential diagnosis. Small fatty tumors are sometimes seen in connection with femoral and inguinal hernias, but these are more of the nature of local hyperplasias of fat tissue than of true neoplasms. Such hyperplasias may in themselves constitute the hernia, and may drag the intestine down into the sac (hernial lipomata). Similar hyperplasias of the epiploic appendages may present the appearance of pedicled lipomata. Subserous lipomata of the anterior abdominal wall may sometimes appear as subcutaneous tumors as the result of the atrophy or displacement of the abdominal muscles. Large fatty tumors of the omentum have also been reported; in several instances the growth presented the character of a myxolipoma.

Submucous.—Small pedicled lipomata of the gastro-intestinal submucosa are occasionally found. They are usually of small size, and rarely give rise to symptoms. In a few cases they have been of the size of a man's fist, and when situated at the pylorus or ileocæcal valve, caused obstruction. In other cases they have led to intussusception. In the submucosa of the respiratory tract fatty tumors are more rare. Fatty polypi are sometimes seen in the laryngeal and nasal mucosa.

Intermuscular.—Fatty tumors are occasionally found between the muscles, arising in the intermuscular connective tissue. They may reach a very large size. The myxolipoma is the most common form, and is characterized by a tendency to become sarcomatous. They are found most frequently in the gluteal folds, thigh muscles, and muscles of the neck. Congenital lipomata have been found in the muscles of the anterior abdominal wall. Enlargement of the sucking disc may give rise to a lipomatous tumor.

Periosteum.—Lipomata of the periosteum are rather rare. As a rule, they also contain striped muscle fibres, and are therefore to be regarded as heterotopous teratomata. In some cases parosteal lipomata have been observed at birth.

Joints.—A diffuse subserous hyperplasia of fatty tissue is not uncommon in the synovial membranes of the joints, the knee- and shoulder-joints being most frequently affected. The hyperplasia of the villous fringes gives rise to an arborescent appearance (*lipoma arborescens*). The movements of the joints may be affected. These conditions are not to be classed with the true lipomata.

Internal Organs.—Lipomata are found more frequently in the kidneys than in any other of the internal organs. The tumors may arise either from the fatty or fibrous capsule, or from the interstitial connective tissue of the cortex and medullary pyramids. They are usually of small size, but occasionally become so large as to be of clinical importance. In the capsule the tumors may represent local fatty hyperplasias or metaplasias; in the kidney cortex they are probably heterotopous teratomata, though it is possible that they arise in some cases directly from the interstitial connective tissue of the organ or represent a metaplasia of a fibroma or of a mass of scar tissue. Many growths described as kidney lipomata were in reality "adrenal rests." The writer has reported a unique case of fibrolipoma of this organ which was so large as to cause serious clinical symptoms and to require operative interference. The growth, of which an illustration is here given (Fig. 5158), was a lobulated mass fourteen inches long, eight inches wide, and six inches in thickness, weighing two pounds. It completely filled the enormously dilated pelvis of the left kidney, and sent a round cord-like prolongation down into the dilated ureter. The only remains of kidney tissue were found microscopically in the cyst wall enclosing the tumor, which was entirely free except for a pedicled attachment posteriorly. At this point the tissues of the tumor passed into those of the cyst wall. Microscopically the tumor presented the structure of an œdematous fibrolipoma, its surface being covered with a layer of atrophic transitional epithelium derived from the kidney pelvis.

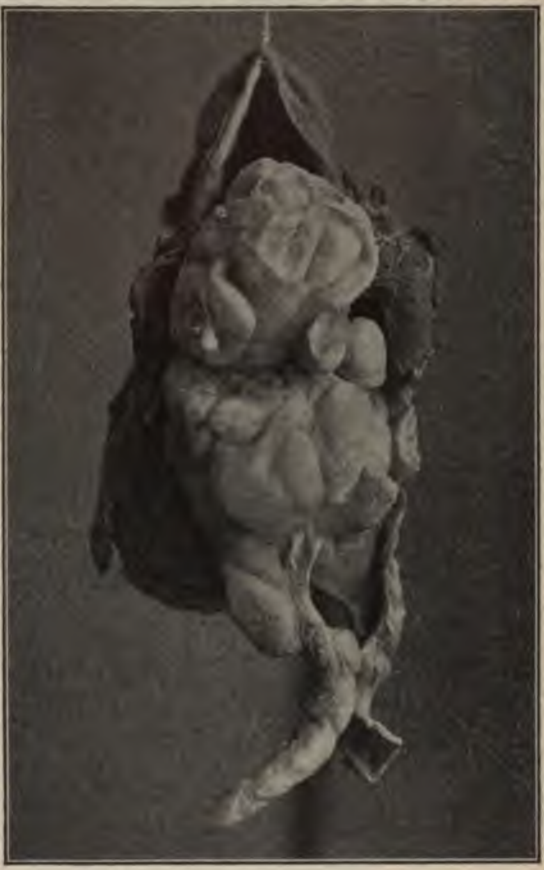

FIG. 5158.—Fibrolipoma of the Kidney. (Warthin.)

Lipomata of the *heart* are very rare. The majority of cases reported as such were most probably conditions of excessive fatty infiltration. According to Orth, small lipomata are sometimes found under the epicardium near the apex. Albers, Banti, Handford, Pasini, and others have reported the occurrence of lipomata arising in the intermuscular connective tissue. The cases described as lipomata of the *liver* and *spleen* are very doubtful. Those found upon the capsule of these organs probably represent portions of omentum or epiploic appendages that have become loosened. A formation of adipose tissue may occur also in old adhesions. Lipomata of the *ovary* have apparently not yet been observed. In the *uterus* tumors of the nature of lipomyoma or fibrolipoma have been seen in a few cases. Fatty tumors of the *broad ligament* are very rare. Very large lipomata are occasionally seen in the *vulva*. They may increase in size during pregnancy. Small ones are found rarely beneath the skin of the *scrotum*. Connected with the *spermatic cord* there are found sometimes lipomata of considerable size. Some of the smaller tumors of the cord described as lipomata may have been adrenal tissue (adrenals of Marchand). In the *central nervous system* lipomata are found rarely. They arise usually from the meninges, but fatty tumors have been found in the substance of both brain and cord. In the case of the brain, they appear to be found most commonly in connection with the corpus callosum. They are probably of the nature of heterotopous teratomata. In the complex teratomata of the nervous system a large part of the tumor mass may be made up of fat tissue. Fatty tumors are also not infrequently found in the sacral and lumbar regions in connection with spina bifida occulta.

Retrograde Changes.—According to Virchow, it is not rare to find in lipomata isolated cavities the contents of which are partly fluid and partly saponified. Saponifying necrosis of lipomata has been reported by a number of observers ("soap cysts," "butter cysts"). The necrotic areas appear whitish, opaque, and of a cheesy consistence. Lime salts may be deposited in such necrotic areas, and in this way there may be formed calcareous nodules throughout the growth. A deposit of lime salts may occur also within the stroma of the tumor. In some cases the entire growth may become calcified. Ossification has also been reported as occurring within lipomata. Liquefaction of portions of the fat tissue may occur. Through the rupture and confluence of fat cells pseudocysts filled with oil may be formed (oil cysts). The twisting of the pedicle of a polypoid lipoma may lead to the necrosis and sloughing of the entire tumor. Self-healing may result in this way. In some cases a serous atrophy of the fat tissue takes place, the tumor assuming the character of an œdema and partial liquefaction of the fat tissue. The fat may be removed from the cells and the lipoma changed into a fibroma. Myxomatous degeneration converts the tumor into a myxolipoma. This is the most common retrograde change occurring in fatty tumors; and is of the nature of a metaplasia. Retrograde changes are most common in the lipomata of the skin, since in this location the tumors are most exposed to injury and to the possibility of infection.

Diagnosis.—The nature of the gross appearances, the clinical history, etc., make the diagnosis easy in those cases in which the tumor can be seen and directly palpated. The subcutaneous lipomata are slowly growing, lobulated, movable tumors, and give pseudofluctuation. In the case of large lipomata of the internal organs the negative results of aspiration in the case of a fluctuating tumor would lead to the suspicion of lipoma, particularly in the case of retroperitoneal tumors. The presence of inflammatory changes and the development of cachexia are suggestive of sarcomatous change. Neuralgic pains may be associated with lipomata. The symptoms in general are dependent upon the position and size. Lipomata of internal organs may give rise to important pressure symptoms. In the great majority of cases, however, the only effect is a cosmetic one. In spite of the great size to which they frequently attain lipomata do not usually influence the general metabolism of the body.

Prognosis.—The prognosis in lipoma is favorable. Since this form of tumor produces no metastases it must be classed with the benign neoplasms. Sarcoma may develop in a lipoma, but this occurrence is very rare, more so than in the case of any other of the benign connective-tissue tumors. Sarcomatous change appears to be more common in the case of tumors containing both adipose and myxomatous tissue (myxolipoma), the resulting sarcoma being of the nature of a myxosarcoma. This change occurs most frequently in lipomata of the intermuscular connective tissue. The cases reported in the literature as metastatic lipomata are undoubtedly examples of sarcomata containing fat tissue. No evidence exists of the metastasis of a pure lipoma. As a rule, the growth of a lipoma is gradual and slow, with periods of apparent quiescence. In the case of infected lipomata, particularly those of the skin, the prognosis is more grave, since the conditions favor the occurrence of phlegmonous inflammations with resulting septicæmia or pyæmia. Such complications are, however, on the whole rare. In the case of large lipomata of internal organs the prognosis depends upon the location of the growth, the extent of the pressure symptoms, the organs thus involved, etc. The removal of a lipoma usually results in a cure, recurrence being very rare.

Treatment.—The treatment is purely surgical. In the case of subcutaneous lipomata local anæsthesia is usually sufficient. It should be borne in mind that the capsule should be removed in all cases of lipoma, since very often the new formation of fat tissue proceeds from the fibrous capsule. In the case of the diffuse forms the prolongations of fatty and fibrous tissue extending into the surrounding tissues should be dissected out, as from these a recurrence may take place. In those cases in which the tumors are covered by atrophic or inflamed skin the incision is best made at the base of the growth and not over it. Tearing should be carefully avoided. Drainage is not necessary. The strictest aseptic precautions should be observed during the operation and afterward, since the condition of the tissues about the growth favors infection and the occurrence of phlegmonous inflammations.

Aldred Scott Warthin.

LIVER, TUBERCULOSIS OF THE.—Without exception all writers agree as to the rarity of primary tuberculosis of the liver, a number going so far as to affirm that an undoubted case of primary hepatic tuberculosis has not yet been reported. Such an apparent immunity on the part of this organ to tuberculous infection cannot be explained by any lessened opportunities for infection, as compared to other organs, such as the kidneys, testicles, etc., in which a primary tuberculosis of clinical importance is not so rare. Indeed, it would appear that the liver with its large extent of vascular surface and the relatively slow circulation in its blood spaces would stand a very good chance of infection from tubercle bacilli that have gained a cryptogenic entrance into the blood stream. Further, the fact that tubercle bacilli may be taken into the alimentary canal in the food and drink would lead to the supposition that the portal veins would constitute one of the avenues of tuberculous infection. These considerations would make it seem probable that primary hepatic tuberculosis would occur more often than we actually find to be the case. It is the opinion of the writer that small healed primary tubercles not infrequently occur in the liver. As is well known to every pathologist, small nodules of hyaline connective tissue varying in size from that of a pinhead to that of a pea are not rare in this organ. By the majority of writers they have been regarded as small fibromata or healed gummata. The fact that some of these little nodules consist of a caseous centre surrounded by a connective-tissue capsule, and that others present an earlier stage of caseating epithelioid tissue with beginning encapsulation, has led the writer to regard the majority of such nodules as healed tubercles. Similar small fibroid nodules are also frequently seen in the spleen and kidneys and are similarly interpreted. If the probabilities of infection, the not infrequent occurrence of healed tubercles, and the extreme rarity of primary hepatic tuberculosis of clinical importance be considered, it would seem that the liver possessed a relatively high resistance to tuberculosis.

Such a relative immunity undoubtedly exists in the œtal liver. A number of cases have been reported of naternal tuberculosis in which the liver of the fœtus ontained great numbers of tubercle bacilli (as shown by taining and animal inoculation) without histological esions of tuberculosis. Such a case has recently been eported by the writer. The seven-months fœtus of a oman dying from acute miliary tuberculosis was examıed carefully for evidences of congenital tuberculosis. he placenta presented a marked miliary tuberculosis. ubercle bacilli were found in the hepatic vessels of the etus, and the inoculation of a guinea-pig with an emulon of fœtal liver gave positive results. Agglutination rombi were found in the liver capillaries, but no histogical evidences of tuberculosis. Several cases, hower, have been reported of probable congenital tuberculis in which tuberculous lesions were found in the er, the infection being regarded as taking place through umbilical vein from the placenta. These cases are refore to be classed as primary hepatic tuberculosis.

f primary tuberculosis of the liver is rare, secondary olvement of this organ is one of the most common hological findings. Not only in cases of acute miliary erculosis are great numbers of tubercles found in this an, but also in all advanced cases of chronic pulmoy and bone tuberculosis. Even in cases in which the ase of the lung is not very extensive scattered secary tubercles may be found throughout the liver. rule, these secondary tubercles are very small, and t is rarely possible to recognize them by the naked at autopsy, they are frequently overlooked. In the t majority of cases their presence can be demoned only by microscopical examination. The larger (size of a mustard seed to that of a pea) are grayish, translucent, with yellowish opaque centres. They e best seen in the livers of children where they often everal millimetres in diameter. The infection is usuhæmatogenous, and the microscopical picture pred is that of a disseminated miliary tuberculosis of gan. Occasionally larger caseous nodules are found nnection with miliary tubercles, and more rarely culous cavities or abscesses. Still more rarely there und large solid caseous nodules in the liver resemthe solitary tubercles of the brain. These may be en for cancer nodules or gummata. Such large es may not show any especial connection with the ıcts, and it is probable that in some cases they repprimary tubercles.

number of the miliary tubercles may be so great ch section may be full of them; in other cases it e necessary to examine many sections before a le is found. In the case of pulmonary and bone ulosis and general miliary tuberculosis the infecthe liver is usually through the hepatic artery; case of intestinal tuberculosis it may take place h the portal vein or lymphatics. The tubercles, tion either through the hepatic artery or through tal vein, are found chiefly at the periphery of the nd in the interlobular connective tissue. A small may be found in the intermediate and central the lobule. As the nodules increase in size they n from the periphery and cause a destruction of cells.

riter believes that in the great majority of cases st step in the formation of a liver tubercle is an ation thrombosis in the liver capillary. The nd growth of tubercle bacilli upon the endothethe capillary wall and the consequent injury to thelial cells are probably chiefly responsible for mbosis. As a result of the thrombosis and of y to the endothelium, as well as from the forf toxins, the neighboring liver cells undergo degeneration or necrosis. There is a collection of leucocytes at the affected point, and these may also undergo necrosis. Following the degenerative changes there is a proliferation of the endothelium and of the neighboring connective tissue leading to the formation of an epithelioid tubercle which sooner or later shows a central caseation. The smallest tubercles may show no inflammatory reaction about them. Giant cells may be present in large or small numbers, or may be entirely absent. They arise from the proliferating endothelial and connective-tissue cells, and possibly also from the leucocytes. As the nodules increase in size they may become confluent. As the result of an interstitial infiltration about the tubercles the picture of a diffuse cirrhosis may be presented, newly formed connective tissue being found not only between the lobules, but also growing into the latter. The greater the number of tubercles the closer the resemblance to a cirrhosis. An increase of the small bile ducts may be observed in the neighborhood of the tubercles. A true atrophic cirrhosis may result, but usually death occurs before this condition has time to develop. It should be remembered also that the tuberculosis may occur secondarily in a cirrhotic liver.

In very acute cases of general miliary tuberculosis with a high degree of virulence the only lesions found in the liver may be areas of focal necrosis of the liver cells. These areas may be so large as to be easily seen with the naked eye. The blood spaces of the necrotic areas are filled with fibrin and agglutinated red cells. Large colonies of tubercle bacilli may be found in the necrotic foci. No proliferation of the endothelium or connective tissue may be present; giant cells are entirely absent. The process can be recognized as tuberculosis only by staining for tubercle bacilli. The writer has seen two cases of this kind which were diagnosed as typhoid fever; the autopsy showed large focal necroses in liver, spleen, and kidneys, those in the liver and spleen being most numerous and largest. No epithelioid proliferation or giant cells were found about these areas, and the tuberculous nature of the process was recognized only on staining for tubercle bacilli, when each caseous focus was found to contain great numbers of the latter. In general miliary tuberculosis of a less virulent type small focal necroses of this kind are also found in association with epithelioid, lymphoid, and caseating tubercles. It is also to be noted that in such cases the lesions in the liver are usually smaller than in other organs, and this fact may also be taken as an indication of a greater resisting power on the part of the liver to tuberculosis.

In the case of hepatic tubercles occurring secondarily to chronic tuberculosis of other organs the liver may show such changes as amyloid and fatty infiltration. The latter change is practically always present. In chronic pulmonary tuberculosis the liver shows usually a more or less marked chronic passive congestion (nutmeg liver). In acute miliary infections the liver cells show cloudy swelling, fatty degeneration, or simple necrosis.

Hanot and Gilbert distinguish the following forms of hepatic tuberculosis:

1. Acute hépatite tuberculeuse graisseuse hypertrophique.
2. Subacute. (*a*) Hépatite tuberculeuse graisseuse atrophique ou sans hypertrophie; (*b*) hépatite tuberculeuse parenchymateuse nodulaire.
3. Chronic. (*a*) Cirrhose tuberculeuse; (*b*) foie gras tuberculeux (without tubercles).

A rare complication of hepatic tuberculosis is secondary carcinoma of this organ. Several cases of this kind have been reported, and the writer has seen a similar case in which both the tuberculous infection and the metastasis of the carcinoma were through the portal vein.

More rare than secondary miliary tubercles of the liver are larger caseous nodules, the centres of which contain cavities filled with bile-stained caseous material. These cavities may be of the size of a walnut. The process represents a tuberculosis of the bile ducts, the walls of which become caseous. The infection is probably lymphogenous, and has the character of a tuberculous periangiocholitis. In very rare cases the infection may take place through the bile ducts themselves. In the great majority of these cases, however, the tuberculous process begins around the bile duct and invades its mucosa only secondarily. Hæmatogenous hepatic tubercles may or may not be associated with this condition.

The liver and the peritoneum may be involved at the same time, but this organ is rarely involved from the latter or from the omentum.

In experimental hepatic tuberculosis in animals the process runs a more acute course, being characterized by larger areas of necrosis.

The clinical symptoms of hepatic tuberculosis are slight, and the condition can but rarely be distinguished from the miliary or chronic process with which it is associated. The occurrence of icterus or the rapid development of a painless ascites points to the development of tuberculosis of this organ. In children the organ may become enlarged and sensitive. *Aldred Scott Warthin.*

MICTURITION, DISORDERS OF.—Given normal urine and a normal genito-urinary tract, micturition is accompanied and followed by no other sensation than one of relief, and is performed normally from four to twelve times in twenty-four hours, depending upon the temperature and humidity of the air, the amount of exercise taken, the intensity of the mental occupation and the degree of anxiety which it entails, the volume of water drunk, and—to a less extent—upon the kind of food ingested.

Many of the disorders of micturition are directly augmented or exaggerated by excessive acidity of the urine on the one hand, or excessive alkalinity on the other; a few of the disorders are directly caused by these conditions.

With rare exceptions the several disorders are interdependent and correlative. No one disorder may be said to occur alone.

For convenience in reference, the disorders of micturition are given alphabetically; but the several possible causes of each disorder are arranged as nearly as possible according to the relative frequency of their clinical occurrence.

Diminished Stream.—This disorder may be either (1) temporary, or (2) constant until relieved by surgical intervention.

1. When temporary or of short duration a diminution in the size of the stream points to a transient obstruction, *e.g.*, congestion at some point or zone in the urethra or a urethral spasm.

As a result of inflammation, any part of the urethral canal may become swollen to the extent of obstructing the urinary stream to a greater or less extent. Thus we may have a diminished stream due to a severe acute urethritis affecting the anterior urethra, with or without involvement of the posterior urethra. It may also be observed in connection with an acute prostatitis.

Any lesion of the urethra—*e.g.*, organic stricture, especially if irritable, or a granular patch—is capable of exciting urethral spasm, especially in neurotic individuals. The diagnosis must be made partly by exclusion, but chiefly by exploration of the urethra with a bougie-à-boule, sound, and endoscope.

2. A diminished stream which either shows no tendency to grow larger or undergoes a progressive further diminution in size, points to an organic obstruction. In all cases of this nature of long standing the resulting atony of the bladder plays an important though secondary part in the character of the stream.

Organic stricture, when neglected, gives a stream which tends constantly but slowly to diminish in size. If the stricture be situated at or near the meatus the stream will be small and scattering, but forcible; if it be situated deeper within the canal. the forcible projection will be lacking. When the stricture becomes inflamed from any cause, the diminution progresses rapidly and may persist until complete retention results.

Prostatic enlargement has among its early symptoms a diminution of the urinary stream. As micturition begins, the stream is small and feeble, sometimes dribbling; it then becomes larger and, except in the later stages of enlargement of the prostate, attains a fair volume and force, only to become again small and feeble and usually dribbling as the act is completed.

Chronic contraction of the prostatic fibres surrounding the neck of the bladder gives the same symptoms as does commencing enlargement of the prostate. In the differential diagnosis the chief point is the age of the patient; in many cases the diagnosis cannot be made without an exploratory perineal section.

Periurethral abscess may cause a narrowing of the urethra and thus diminish the stream; when situated in the bulbous portion the abscess may cause acute retention.

A partial plugging of the urethra by a small calculus arrested on its way from the bladder produces a diminution of the stream that becomes more marked as inflammatory congestion advances. If the calculus is rough there will follow an oozing of blood from the meatus, unless the urethral mucous membrane happens to be deeply cicatricial at the point of arrest. Palpation along the course of the urethra—per rectum for the posterior portion—rarely fails to detect the calculus. Instrumental exploration usually is conclusive.

A partial plugging of the outlet of the bladder by a pedunculate tumor or a small movable calculus will give rise to a diminished stream accompanied by symptoms more or less pathognomonic of the lesion present. The diagnosis is materially aided by the fact that immediate relief is obtained by dorsal decubitus or by the dislodgement of the obstruction by means of a sound or searcher.

Urethral polypi diminish the stream in proportion to their size. When they are very small there may be no symptom except hemorrhage.

Dribbling.—In addition to the dribbling that characterizes the first and second forms of incontinence, and which is sufficiently described in subsequent paragraphs, still other types of dribbling may be recognized. Thus we have:

1. The involuntary, painless escape of a few drops of urine at the end of micturition.
2. The voluntary, not always painless, escape of a few drops of urine at the beginning of micturition.
3. The urine is voided in drops throughout micturition.

(1) In prostatic enlargement the dribbling of a few drops of urine at the end of micturition is a common and early symptom. It is independent of the degree of vesical atony which may be present; in fact, it may exist without the presence of any vesical atony whatever.

In chronic urethritis (anterior or posterior or both) the dribbling, when present, is constant until the muscular tone of the urethra has been restored.

In stricture of the urethra of large calibre the final drops of urine are caught behind the stricture and dribble out into the clothing.

In chronic contraction of the prostatic fibres surrounding the neck of the bladder the dribbling at first is an intermittent symptom; later, it is constant.

(2) In prostatic enlargement the voluntary and not always painless escape of a few drops of urine occurs at the beginning of micturition. It is preceded by hesitancy and gradually gives way to the full stream, which in turn dies away and ends with dribbling.

(3) In filiform stricture of the urethra, if it has existed for a relatively short period of time, and consequently is associated with only slight atony of the bladder, the stream is of a dribbling character, and is produced with more or less effort.

In acute prostatitis (including prostatic abscess) and in acute seminal vesiculitis the urine is voided in drops when retention threatens, either from mechanical obstruction or as the result of reflex irritation.

Frequency and Urgency; Pain and Tenesmus.—Frequency of urination may be normal, or physiologic, within wide limits. It is abnormal, or pathologic, when

accompanied by urgency, pain or tenesmus, or when due
to a tangible, pathologic condition or to that obscure
pathologic state called a neurosis. Frequency rarely oc-
urs without at least a trace of urgency; frequency and
rgency are practically never without a degree of initial or
rminal pain and tenesmus. Frequency due to quan-
ity alone is not included, it being dependent, strictly
peaking, upon a disorder of elimination.

In acute posterior urethritis, when this is severe, fre-
uency and urgency are marked; a lesser grade gives
nly frequency; the mildest grade of all does not occa-
on any disorder of micturition. In every case of acute
sterior urethritis a digital rectal examination should be
ade to ascertain whether acute prostatitis and acute
minal vesiculitis are present.

In chronic posterior urethritis there is, in most cases, a
ry trifling frequency which shows a tendency to in-
ase and may become complicated by urgency, as well
occasionally by pain and tenesmus, during an exacer-
ion of the local congestion. In a few cases frequency
onstant, and is accompanied by more or less urgency
l slight initial and terminal pain, with very moderate
esmus.

n organic urethral stricture the frequency is due to
maintenance of a chronic posterior urethritis. Usu-
it is diurnal only. Later on, chronic partial retention
lded, and, the symptoms becoming exaggerated by
congestion due to this retention, urgency and pos-
pain and tenesmus develop.

acute prostatitis and acute seminal vesiculitis (in-
ing prostatic abscess) there may be, in the early stage,
ly increased frequency, but usually both this symp-
and urgency coexist from the outset, and with them
ssociated more or less pain and tenesmus. Very
there is no disorder of micturition. Digital rectal
ination affords the only means of establishing the
osis.

chronic prostatitis and chronic seminal vesiculitis
ht, uncomplicated, diurnal increase in frequency is
acteristic of the disease. It tends to increase and
cy develops during the occasional mild exacer-
s to which the coincident posterior urethritis is

rostatic enlargement, uncomplicated increase in
ncy, especially if nocturnal, in a man forty-five
f age or older, who gives no history of a previous
e in frequency, is pathognomonic of the early
of this affection. The frequency increases with
argement, and sooner or later becomes diurnal as
Still later it becomes complicated by urgency and
d then by tenesmus, all of these depending upon
ree of prostatitis and urethrocystitis that have
ed, and in some cases (especially those of an ad-
type) upon the presence or absence of a calculus.
rieties of acute cystitis cause increased frequency
rition. If the inflammation be severe, or if it
bout the neck of the bladder, as it commonly
re will be extreme frequency with urgency,
tter symptom may amount to a slight inconti-
occasions. There will also be pain and tenes-
latter sometimes amounting to strangury. As
owever temporary relief quickly follows the
pain and tenesmus.

nic cystitis frequency of micturition may be
ring the quiescent periods and during mild ex-
s. Urgency is rare. Unusual frequency with
pain and tenesmus, denotes a sharp exacerba-
-recurring exacerbations in cases with little or
tic enlargement furnish strong presumptive
he presence of a calculus in the bladder; and
exacerbations occur in cases in which the
enlarged, they indicate either that a fresh in-
taken place, or that there is a calculus in the
both. When a sharp hæmaturia accompanies
ations a differential diagnosis will be required
ceration—simple, gonorrhœal, or tuberculous,
s, and a neoplasm.

lculus is present in the bladder, diurnal rather than nocturnal increase of frequency is a characteristic of the condition. Micturition is usually accompanied by pain, sometimes also by tenesmus, depending upon the size of the calculus, the character of its surface, and the degree of cystitis. Thus the increased frequency may become practically incontinence. The terminal pain is referred usually to a point about an inch back from the meatus. When the calculus is small and mobile, and therefore capable of rolling against the vesical outlet, there occur sudden attacks of increased frequency, urgency, pain and tenesmus, with a minimum of cystitis. Recumbency lessens the suffering; occasionally it gives complete relief. Exercise, especially that which jolts the pelvis, aggravates the symptoms.

In pyelitis, when acute and of high grade, the frequency, urgency, pain, and tenesmus referred to the neck of the bladder, may simulate vesical calculus. Chronic pyelitis gives at most a slight increase in frequency of micturition.

The presence of a small tumor in the bladder, if it be seated at a point remote from the outlet, may not affect micturition. In a case of this character an uncomplicated hæmaturia is the only symptom that would point to the presence of the tumor. Larger tumors produce increased frequency which is in direct proportion to their size; they also produce urgency, pain, and tenesmus, all of which symptoms depend for their severity upon the location and mobility of the tumors. This applies also to polypi in the prostatic urethra.

In ulcer of the bladder, simple, gonorrhœal or tuberculous, urgency depends upon the proximity of the ulcer to the vesical neck. If it be situated within the neck, there will be more or less pain and tenesmus, sometimes initial as well as terminal, with more or less hæmaturia.

In vesical tuberculosis an otherwise unaccountable increase in frequency, diurnal and nocturnal, is an early symptom. Cystoscopy often aids in the diagnosis. Later, the presence of urgency, pain, and tenesmus, and their severity, depend upon the proximity of the lesion to the vesical neck and upon the extent of the lesion independently of its location. In advanced cases the pain and tenesmus usually are very severe and may be accompanied by hæmaturia. A negative examination for tubercle bacilli in the urine is not conclusive.

In renal tuberculosis, renal calculus, and ureteral calculus, when not complicated by cystitis, these affections may give rise to an uncomplicated diurnal increase in frequency. Renal colic, due to any one of the above causes or to movable kidney, may be accompanied by reflex increase in frequency, urgency, pain, and tenesmus.

Among the acute symptoms associated with intermittent hydronephrosis there is usually more or less increase in frequency of micturition, often accompanied by urgency, pain, and tenesmus; the severity of these symptoms depending upon the cause of the hydronephrosis. As the attack subsides and the pent-up urine is liberated, there is likely to be a slight, uncomplicated, transient increase in frequency due to the sudden increase in the quantity of the urine.

In tuberculous prostatitis the incipient stage and occasionally a more advanced stage give, as a rule, no urinary symptoms. When the disease is well advanced it causes increased frequency and more or less urgency, accompanied by terminal pain and tenesmus so sharp as to simulate vesical calculus. The diagnosis is established by exclusion and by the discovery of nodules in the prostate on digital rectal examination. A negative examination for tubercle bacilli in the urine is not conclusive.

Increase in frequency of micturition occurs as a neurosis in young and neurotic individuals, and possibly also in neurasthenic men. The increased frequency is diurnal and may become exaggerated by the large quantity of urine which these patients sometimes excrete. In some cases any attempt to postpone the act of micturition causes severe pain. The differential diagnosis between this neurosis and incipient vesical tuberculosis is sometimes difficult without the aid of cystoscopy.

In hernia of the bladder, before cystitis has developed, increase in frequency is the only urinary symptom. The pathognomonic signs are: a more or less tense, fluctuating tumor in the usual site of an inguinal hernia; its disappearance under gentle manipulation while the patient is recumbent; his ability to rise and void another volume of urine, although he emptied his bladder immediately before the reduction; and, finally, the reappearance of the tumor when the bladder is distended with fluid.

In contracted bladder the increase in frequency is as pronounced during the night as it is during the daytime. When the contraction is due to interstitial changes following long-standing chronic cystitis from any cause, or when it is due to advanced tuberculosis, progressive or stationary, there are increased frequency, some urgency, and more or less terminal pain and tenesmus.

Two very rare conditions—a congenitally small bladder and an undeveloped bladder due to a long-neglected incontinence in childhood that has resulted in the habit of frequent micturition—give equal diurnal and nocturnal increase in frequency as the only symptoms so long as there are no complications.

In chronic lesions of the spinal cord, a degree of increased frequency, which may well be described as an irritability of the bladder, is common in the earliest stages. Later on, there occurs an increase in frequency which is dependent upon distention of the bladder.

Hesitancy or Slowness in Starting the Stream.—As a pure neurosis hesitancy is very common; it is seen in the difficulty which certain patients experience when they attempt to urinate in a hurry or in the presence of others.

In prostatic enlargement hesitancy is an early and practically constant symptom. In chronic contraction of the prostatic fibres surrounding the neck of the bladder it is equally common.

In acute inflammatory conditions of the urethra hesitancy is due either to urethral spasm as such, or to an inhibitory effect through fear of the *ardor urinæ*.

Chronic lesions of the urethra—*e.g.*, granulations or an irritable stricture—sometimes produce a momentary urethral spasm.

In acute and chronic inflammatory affections of the prostate and seminal vesicles hesitancy may result either from the slight mechanical obstruction offered or from a slight urethral spasm.

Painful diseases of the rectum—*e.g.*, ulcer, fissure, or inflamed hemorrhoids—not infrequently produce a momentary urethral spasm.

Incontinence.—Three forms are recognized: 1. A constant, passive, more or less continuous flowing away of the urine. 2. An involuntary escape of a few drops of urine on occasions. 3. An inability to retain sufficient urine in the bladder to constitute an act of micturition, or the constant voluntary—sometimes involuntary—emptying of the bladder by the expulsion of a few drops very frequently. (The nocturnal enuresis of children is not included, as it does not come properly under the title of this article. See *Enuresis*.)

1. This first form is true incontinence. Ordinarily it occurs under only two conditions: (*a*) overdistention of an atrophic bladder; (*b*) atony of the vesical sphincters, with or without atrophy.

Prostatic enlargement is the most classic cause of overdistention with atrophy and therefore of true incontinence in a man past the age of fifty-five. The incontinence is chiefly, if not wholly, nocturnal. Filiform stricture of the urethra, if of long standing and associated with marked atony of the bladder, bears the same relation to true incontinence in younger men. Here the incontinence is chiefly diurnal, and often alternates with acute retention.

Among the diseases of the spinal cord locomotor ataxia (tabes dorsalis) and other scleroses often cause atony of the bladder, thus permitting overdistention and true incontinence. Spastic contractions of the vesical sphincters will foster the overdistention; sensory disturbances causing anæsthesia of the region will augment the incontinence. On the other hand, the reverse—viz., atony of the sphincters and hyperæsthesia—may obtain.

2. This form of incontinence presents many grades and is a symptom of several different lesions. The occasions on which it occurs are: exacerbations in the causative lesions, and any sudden unusual pressure upon the bladder, such as takes place in coughing, sneezing, jumping, or lifting a weight. The causative lesions are: chronic posterior urethritis; ulcers near the neck of the bladder, simple, gonorrhœal, or tuberculous; vesical calculi; vesical tuberculosis, especially when affecting the neck, whether with or without ulceration; renal tuberculosis ("slight incontinence with frequency, in the absence of other lesions, is strongly suspicious of renal tuberculsis"); contracted bladder due to antecedent extreme pericystitis or interstitial cystitis; chronic prostatitis; slight atony, or "relaxation," of the vesical sphincters without atony of the bladder.

3. This is the least characteristic form of incontinence. It is merely an extreme frequency with uncontrollable urgency, and is therefore complicated by more or less pain and tenesmus. The lesions that cause it are: severe acute posterior urethritis; acute cystitis; a large rough, movable calculus, or a collection of facetted calculi, occupying the cavity of the bladder and partially distending it; a small, rough calculus, lodged in the prostatic urethra; renal calculi, causing attacks of severe colic.

Interrupted Stream.—This is also known as the "stammering stream."

The causes of this disorder operate either (1) mechanically, by intermittent obstruction, or (2) reflexly, by intermittent excitation of the vesical sphincter. Under the first class are: Prostatic enlargement; chronic contraction of the prostatic fibres surrounding the neck of the bladder; a small, rounded, mobile calculus; a pedunculate tumor; a blood clot. Under the second class are: Acute, subacute, and chronic urethritis; stricture of the urethra, both of large and small calibre; neurasthenia and neurotic tendencies.

Retention.—Confusion arises from the use of the word retention when suppression is meant. Retention of urine applies only to its discharge from the bladder, while suppression of urine applies only to its excretion by the kidneys.

Retention is due either to a mechanical obstruction, which prevents the escape of urine from the bladder, or to a diminished expulsive power on the part of this organ; this latter condition being due in turn to impaired innervation of the muscle coat, or possibly to some actual lesion of the muscle. In obstructions of long standing the retention is due to a combination of both these factors, for the hypertrophy which developed in the wall of the bladder as a result of its early efforts to overcome the obstruction finally gives way to an atrophy, the degree of which is in direct ratio to the chronicity of the obstruction.

I. Acute Retention.—The cause may be (*a*) organic obstruction; (*b*) spasmodic obstruction; (*c*) a combination of both; (*d*) a sudden impairment of the bladder function, with or without spasm of the sphincter.

(*a*) The following are among the more important organic obstructions: a stricture of small calibre, when inflamed by sexual and alcoholic excesses, by excessive coffee drinking, or by exposure to cold and wet; a prostatic enlargement, when acutely congested or inflamed—a condition to which it is peculiarly liable after any excesses in venery, eating, and drinking, and as a result of constipation; acute prostatitis, simple or gonorrhœal, especially when resulting in an abscess that is pointing toward the bladder; a rupture of the urethra, complete or partial; plugging of the internal meatus, *e.g.*, by a small, movable calculus, a pedunculate vesical tumor, or a blood clot; and, finally, periurethral abscess, especially when located in the bulbous portion. Among the rare organic obstructions should be mentioned: Acute posterior urethritis, severe acute seminal vesiculitis, tuberculous prostatitis, and papilloma of the urethra.

(*b*) Spasmodic obstruction—*i.e.*, obstruction caused

'y spasm of the sphincter—occurs under the following
ircumstances: in acute anterior urethritis, occurring
ither independently or in connection with an existing
rethral lesion (*e.g.*, a stricture or a granular patch); when
ıe urethra is the seat of a comparatively slight trauma,
flicted by a blow, by rough instrumentation, or by irri-
ting injections; when there are rectal lesions, including
ecal impaction and even constipation of only two or
ree days' standing; after operations, minor as well as
ajor, on the urethra or on the rectum or some contig-
ous region, whether performed under local, spinal, or
neral anæsthesia; in the presence of shock, post-opera-
'e or traumatic; as a result of enforced postponement
micturition, especially if there is present any lesion of
e urethra, prostate, or seminal vesicles;* in exhausting
eases, such as typhoid fever, pneumonia, peritonitis,
d meningitis; in vesical tuberculosis; in pyelitis, sim-
:, gonorrhœal, tuberculous, or due to a calculus (the
t-named occasionally causes acute retention instead of
: more usual frequency and urgency of micturition);
hernia of the bladder—a rare occurrence; and, finally,
neuroses and neurotic conditions in general.

:) A combination of organic and spasmodic obstruc-
ns is observed in severe acute posterior urethritis, when
swelling is extreme and when spasm is excited. It is
observed in severe acute prostatitis and in seminal
iculitis.

l) Sudden impairment of the bladder function, with
vithout spasm of the sphincter, may be observed in
ture of the bladder, whether intra- or extraperito-
, and also in those injuries or diseases of the central
'ous system which result in the production of a sud-
hemiplegia or paraplegia, with or without coma.

. Chronic Retention.—This is either partial or com-
:. Chronic partial retention results when only a
ion of the urine is spontaneously voided, the rest
ining in the bladder as "residual urine." Chronic
plete retention exists when all spontaneous mic-
ion has been lost and all the urine has to be drawn
atheter.

prostatic enlargement there is at first only partial
tion. This advances to complete retention if, the
state of affairs not being recognized, the bladder is
'ed to become atonic through overdistention. Thus
the cases of chronic complete retention which have
'ently assumed this character from the outset. An
urrent acute retention is often the first symptom for
ı the patient seeks advice, he having disregarded the
toms of the partial retention.

: remarks made in reference to prostatic enlargement
receding paragraph apply with equal appropriate-
› chronic contraction of the fibres surrounding the
›f the bladder. This chronic contraction, however,
frequent than prostatic enlargement, and conse-
ly it gives rise less often to chronic complete reten-

liform stricture of the urethra the chronic retention
partial; it will disappear after appropriate treat-
›f the stricture unless the latter has been neglected
ny years.

ıronic prostatitis, in tuberculosis of the prostate,
vesical tuberculosis a small quantity of residual
s an almost constant objective symptom.

urther causes of chronic retention may be men-
habitual failure to empty the bladder completely
on of hurry or indifference; and frequently re-
prolonged postponement of micturition, thus
: frequent overdistention.

e the retention which originates in some chronic
f the spinal cord is only partial, it is nevertheless
:rized by a large volume of residual urine—from
wenty ounces. In the mild cases the amount of
lual urine will fluctuate even under the best con-
often falling to two ounces. On the other hand, the amount is fairly constant in the more advanced cases, and the retention is associated with frequency, or with incontinence, or with both. *James Pedersen.*

MOUTH, DISEASES AND INJURIES OF.—I. Stomatitis.—"This word, which from its derivation signifies inflammation of the mouth, is held to include inflammatory affections of the cavity of the mouth as far back as the soft palate. Any abnormal condition of an inflammatory character which involves the gums, the tongue, or the inner surface of the cheeks, is included, therefore, under the designation of stomatitis. Experience shows that there is little tendency toward limitation to any one of these structures—usually the entire cavity of the mouth partakes of the diseased condition.

"The affections included under this name are, in great part, limited to the age of childhood. Adults are never the subjects of certain forms of the disease, and seldom suffer from any variety of it, save as part of some other morbid condition. Not infrequently, however, stomatitis is nothing more than a part of such general condition. Diphtheria sometimes involves the mouth as well as the tonsils, pharynx, and palate; inflammation, with pustulation in the mouth, may occur in smallpox, varioloid, and varicella; facial erysipleas often presents an inflamed condition of the mouth; measles, Rötheln, and syphilis are accompanied by characteristic mouth affections; and many drugs, such as mercury and iodine, in addition to the mineral and other stronger acids, produce an abnormal condition." (From former edition of Reference Handbook.)

It must be remembered that in children there is a tendency to put anything and everything—all germ-laden—into the mouth; hence one reason why stomatitis is so much more common at that age. The troubles incident to the period of dentition have also a causal relation to stomatitis.

As remedies for stomatitis in general, the following have been used. As mouth washes, in the form of solutions: Potassium permanganate, gr. ij. to ℥ i.; potassium chlorate, gr. x.–xx. to ℥ i.; boric acid, saturated solution; carbolic acid, one-per-cent. solution; hydrogen dioxide, 15 vols. per cent.; silver nitrate, gr. x.–xx. to ℥ i. Also the solid stick of silver nitrate may be employed; and potassium chlorate may be given internally in doses of gr. v.–viij. q. 4 h.; in the case of children, however, the latter remedy must be used with care. Tonics of iron, quinine, nux vomica, and cod-liver oil are required. The diet must be liquid, either warm or cold, and must be generous and sufficient; chipped ice and iced water are acceptable to the patient. The mouth must be regularly washed or, if that is not possible, sprayed. If the gums are spongy, they should be painted with tincture of myrrh.

2. Catarrhal Stomatitis.—(*Synonyms:* Acute stomatitis, Erythematous stomatitis, Pultaceous stomatitis, Simple stomatitis, Superficial stomatitis.)

Etiology.—It most commonly occurs in infants and children, but it is also found in adults. The most common cause is an irritant either chemical or mechanical, such as overheated or too highly spiced food, acids, alkalies, very hot beverages, broken or carious teeth, and the excessive use of tobacco or alcoholic drinks. In the case of infants irritation caused by a coral, by difficult dentition, by a poorly developed or unclean nipple, or by a feeding bottle which has not been properly cleansed, may produce stomatitis. An excess of sugar or starchy food, and also exposure to cold, are causative factors in some cases.

Symptoms.—These are the classical symptoms of inflammation: redness, first in patches, later more general; swelling, chiefly of lips, cheeks, gums, and tongue, the latter often showing the impression of the teeth; disordered secretion—in the adult the mouth is at first dry, later there is an increased flow of saliva with secretion of considerable mucus; at the same time the breath is fetid, and in children there is dribbling accompanied with considerable tenderness, so that the infant refuses to nurse or

---

*se cases the spasm is usually of short duration, and it is
nd necessary to resort to the use of the catheter in order to
i-f for the patient.

to allow the mouth to be cleansed. In adults the pain is as a rule slight, though it may be considerable, and, in conjunction with the dryness of the mouth seen in the early stages, renders mastication difficult. The disorder usually lasts about a week. In this form of stomatitis there is no ulceration.

Prognosis is good in acute cases, but infants are liable to suffer from inanition owing to the pain experienced in taking food. In chronic cases, generally due to alcohol or tobacco, the offending substance must be withdrawn.

Treatment is chiefly hygienic; whenever possible the causes must be removed and strict cleanliness insisted upon. In mild cases mouth washes of borax, of potassium chlorate, or of sodium bicarbonate may be useful; in the severer forms silver nitrate in one-per-cent. solution should be applied. At the same time general treatment in the shape of tonics and salines must not be overlooked. In infants the feeding apparatus must be kept scrupulously clean.

3. Croupous or Membranous Stomatitis is an inflammation of the mouth with the formation of a false membrane of a yellowish-white or grayish-white color. The disease may be diphtheritic or it may be due to gonorrhœa or syphilis; it is also caused by extremes of temperature (as frost-bite) and by chemical irritants. This form of stomatitis is much the same as diphtheria, but without the Klebs-Loeffler bacillus. The pseudo-membrane is apt to ulcerate and become detached from the subjacent tissue which then shows marks of erosion.

Treatment.—If the inflammation is due to diphtheria, give antitoxin; in most other cases the treatment is the same as in other forms of stomatitis, and consists of good food, proper hygiene, antiseptic and astringent mouth washes, tonics, and stimulants.

4. Ulcerative Stomatitis.—(*Synonyms:* Fetid stomatitis, Phlegmonous stomatitis, Stomacace, Putrid sore mouth, Phagedenic gingivitis.)

This form of stomatitis is a serious condition in which there is a superficial necrosis of the mucous membrane of the mouth, with subsequent ulceration.

Etiology.—The disease is probably caused by a micro-organism, though none has as yet been isolated. It is generally found in children between the ages of four and fourteen; it may be epidemic, and is apt to accompany or follow improper feeding, infectious diseases, also poisoning by mercury, arsenic, lead, or phosphorus. Unhygienic surroundings and any local irritations are potent factors in this as in the other forms of stomatitis.

Symptoms.—The gums, of the lower jaw chiefly, are spongy, painful, swollen, and bleed readily; later on, the cheeks and lips become affected. The gums also recede from the teeth, which become loosened and may fall out; ulcers may also occur round the sockets of the teeth, and a purulent fluid forms between the gums and the teeth, as well as between the teeth. There are profuse salivation, very fetid breath, and swelling of the neighboring lymph glands. In chronic cases the periosteum of the lower jaw becomes involved, and areas of necrosis ensue. There is great debility, and nausea and diarrhœa, caused by swallowing the profuse fetid saliva, are also apt to be present.

Treatment is on the same lines as in other forms of stomatitis. On account of the disagreeable odor of the breath the patient should be isolated. Mouth washes are required, but in case potassium chlorate is used care must be taken that no untoward results occur, particularly in children. Hydrogen peroxide or dioxide makes an admirable mouth wash.

5. Bednar's Aphthæ, also called *Plaques pterygoidiennes*, or *aphthæ of the palate*, is a variety of ulcerative stomatitis. It is sometimes of traumatic origin, being due to pressure. It occurs generally in bottle-fed children who have unhygienic surroundings and are badly cared for, and is caused by the pressure on the hard palate of an artificial nipple or of the nurse's finger, or of a swab used in cleaning the child's mouth. But in breast-fed children it may also be found; it is then caused by the pressure of the infant's tongue on the thin mucous membrane, during the act of nursing. As a rule the affection is of a mild character, and is found on the hard palate near the alveolar process, but in badly neglected cases the ulceration may be both deep and extensive. In mild cases no special treatment is required beyond the removal of the cause; while in more severe cases a five-per-cent. solution of silver nitrate should be applied.

6. Aphthous Stomatitis.—(*Synonyms:* Follicular stomatitis, Vesicular stomatitis, Herpetic stomatitis, Aphthæ, Canker.)

In this form of stomatitis, which is more common than the catarrhal variety, the mucous membrane of the mouth is hyperæmic and is characterized by grayish or yellowish vesicles which are liable to ulcerate, and are chiefly found on the margin and frænum of the tongue, and on the cheeks; also on the inner surface of the lower lips, near the junction with the gums.

Etiology.—It is probably due to some specific germ, but none has yet been isolated. It is found most commonly in children, and, if not idiopathic, is due to improper food, indigestion, one of the fevers, lack of hygiene and general uncleanliness of the mouth.

Symptoms.—The child is fretful on account of the pain; dull and feverish; the mouth is hot; the saliva flows freely and may irritate or excoriate the chin and neck. The ulcers described above are surrounded by red areolæ and bleed readily if any attempt is made to remove the grayish-white base. The process lasts about a week.

Prognosis is good. The sores may be treated with silver nitrate; local washes of potassium chlorate or potassium permanganate should be used; food, tonics, and stimulants are required.

7. Parasitic Stomatitis.—(*Synonyms:* Mycotic stomatitis, Stomatomycosis, Thrush, Muguet, Soor.)

Thrush is one form of parasitic stomatitis, but it is the most important variety. The disease is due to a vegetable parasite, and consists of white flake-like patches on the mucous membrane of the mouth and tongue. These patches consist of epithelium, leucocytes, and the spores and filaments of a fungus. The fungus or mould has been described as oïdium albicans, saccharomyces albicans, oïdium lactis, mycoderma vini, and monilia candida. The fungus displays remarkable polymorphism, having a great tendency to spore formation in a solid medium, and to filament formation in a liquid medium. The fungus tends to grow rapidly, particularly upon an unclean surface. The spores lodge between the epithelial cells; then separating the different layers and destroying the superficial layer they penetrate down into the connective tissue. The disorder is apt to become epidemic in institutions where there are many children, being transmitted by unclean feeding apparatus. The spots or patches look like curdled milk, but are covered with epithelium and are readily removed without bleeding, being thus differentiated from aphthous or follicular stomatitis.

Etiology.—The disorder is found generally in childhood, and occurs in the debilitated or uncleanly, more particularly in bottle-fed infants. It is apt to follow catarrhal stomatitis; and the growth of the fungus is favored by mouth breathing and by the restricted movements of the tongue which are necessitated by many forms of stomatitis.

Symptoms.—The symptoms are as a rule slight and much like those of catarrhal stomatitis. The saliva is acid and decreased in quantity; and the mouth is apt to be dry.

Treatment, as in other forms of stomatitis, consists in absolute cleanliness, the employment of mouth washes of an antiseptic character, the observance of a proper hygiene, and the administration of good food, tonics, and stimulants.

8. Gangrenous Stomatitis.—(*Synonyms:* Noma, Cancrum oris, Water cancer.)

This is an uncommon but very formidable complaint, and is almost invariably found in young children. It is favored by poor hygienic conditions, lack of food, and general enfeebling diseases. It may follow an ordinary ulcerative stomatitis, but the two conditions are very different. Probably some micro-organism is the cause of the disease, but so far it has not been isolated. Cancrum oris must not be interpreted as an ordinary gangrene of a local character, for the blood supply of the face is far too good to allow of such a supposition. Characteristics of this disease are: (1) that it begins on the inside of the cheek; (2) that it is almost always unilateral, though cases have been reported in which both cheeks were attacked; (3) that it perforates the whole thickness of the cheek; and (4) that it is rapidly fatal. At first there will be observed a small red swelling on the inside of the cheek, often opposite the opening of Stenson's duct. This small swelling gives place to a large, rapidly growing ulceration and is followed by gangrene. The destructive process begins from within and works outward. The whole thickness of the cheek is soon involved; it becomes brawny, and the outside is red and glazed; perforation soon occurs. The breath is fetid, the teeth fall out, the jaw becomes necrosed, and the whole process is marked by the extraordinary rapidity with which it advances, a rapidity so great that in from one to two weeks the patient dies either from exhaustion or from pyæmia. "The intelligence remains generally undisturbed, and the little patients do not seem to be greatly alarmed, but rather apathetic. The temperature and respiration become influenced principally because of, and in proportion to, the inflammation of the lungs, which is frequently a precedent and concomitant condition. This associated pulmonary inflammation is, however, never of the sthenic type of simple acute lobar pneumonia." (From former edition of Reference Handbook.) "Diagnosis in the later stage is rendered unmistakable by the ulcer, nodule, slough, and perforation. The early stage is to be distinguished from malignant pustule (anthrax). The latter begins as a pustule upon the outside of the cheek, often at the site of an abrasion; it is far more common in adults, and the anthrax bacillus is discoverable in the pustule and blood." (Thompson's "Practical Medicine.") There is very little pain, but much prostration, and generally there are nausea and diarrhœa.

The *prognosis* is bad; different writers place the death rate at between eighty and ninety-five per cent.

Treatment to be of any use must be vigorous and early. Free extirpation or the application of the cautery should be early resorted to; there should be frequent applications of hydrogen dioxide, and tonics and nourishing food should be administered every two or three hours.

9. Mercurial Stomatitis. — (*Synonym:* Mercurial ptyalism.)

This is an inflammation of the mucous membrane of the mouth and gums, due to the use of mercury; it is rarely found in syphilitics.

Symptoms.—The patient complains of a metallic taste, tenderness of the gums which are also unusually red, and increased flow of saliva; the tongue becomes swollen and there is difficulty in both mastication and deglutition. The salivation is apt to be extreme; and the odor of the breath is most offensive.

Treatment.—Those working in mercury should cleanse both mouth and teeth frequently; and those taking the drug should at once discontinue its use. The best remedies are salines, alkaline drinks, and atropine to arrest the flow of saliva. During convalescence tonics will be required.

10. Ptyalism, or Salivation, and Xerostomia have been described in Vol. VII. of the Reference Handbook, under the heading *Salivary Glands, Diseases of;* it only remains here to outline the treatment of the former condition. When ptyalism is produced by the administration of mercury, as is (or was) generally the case, the use of that drug should be discontinued, the mouth should be washed with astringent lotions such as alum or potassium chlorate, and potassium iodide should be given internally. Mercurial salivation can often be prevented or diminished by devoting proper care and attention to the condition of the patient's mouth and teeth; it has been asserted that the administration of small doses of potassium chlorate in conjunction with the mercury will also lessen the likelihood of salivation. In ptyalism from other causes the tincture of belladonna has been recommended in doses of ♏ x. t.i.d.

11. Angina Ludovici, or Ludwig's angina, is the name given to an infective inflammation of the floor of the mouth, and of the cellular tissue beneath the deep cervical fascia. It generally begins in the submaxillary glands, and is due to an infection with one or more varieties of the pus-producing bacteria—probably the streptococcus pyogenes—and is accompanied by much swelling and infiltration of the mouth, tongue, throat, and neck. There are severe pain and dyspnœa, the latter being often caused by œdema of the glottis. The patient finds great difficulty in opening his mouth, in talking, and in masticating and swallowing his food. Sloughing of the soft parts is apt to ensue and is called *cynanche gangrænosa.*

Prognosis is not good.

Treatment consists in the employment of antiseptic measures and in making a prompt and free incision into the involved tissue, generally in the median line. Tracheotomy may be demanded for œdema of the glottis. Tonics and nourishing food are indicated. (See also Vol. VI., p. 593.)

12. Perlèche is a contagious disorder consisting of fissures at the angles of the mouth. The trouble is found chiefly in children, and is very painful. It is probably caused by a micro-organism; Le Maistre reporting a streptococcus, and Raymond a variety of staphylococcus in connection with this disorder. It lasts for from ten to twenty days, and is bilateral, beginning at the angles of the mouth, and spreading along the border of the lips. The lips swell and are painful, and are apt to ulcerate. The skin around the mouth is not often attacked, but the mucous membrane is involved and the epithelium becomes white and sodden and is then desquamated. Pain and itching are present, and the child licks the parts to relieve the pain and burning; hence the name, from the French perlécher (= to lick). The disease is spread by drinking-vessels. Treatment consists in cleanliness and the use of astringent lotions of alum, copper sulphate, or even nitrate of silver. A dusting powder of bismuth subnitrate may be used; and, as a prophylactic measure, children should have their own cups to drink out of.

13. Riga's Disease occurs as a gray ulcer with an irregular border situated under the tongue, near the frænum. It appears about the period of first dentition, and lasts for a variable period, usually about a year. It has been found almost epidemic, certainly endemic, in Southern Italy. Its origin is most likely traumatic. The treatment is that of catarrhal stomatitis.

14. Salivary Calculus may occur in the excretory duct of any of the salivary glands, but is most frequently found in Wharton's duct. It consists of phosphate and carbonate of calcium together with sodium chloride and magnesium. After such a concretion is formed, it may either remain in the gland, or be discharged through the duct, or it may obstruct the duct. In the two former conditions it gives no trouble, but in the last case it gives rise to pain and swelling of the gland with which it is connected; the swelling is always increased on taking food. Careful palpation along the course of the duct will help in making a diagnosis; and, except in mumps, pain and swelling in a salivary gland should always suggest salivary calculus.

Treatment consists in making an incision into the duct, either in the distended portion only, or in its whole length from the outlet to the obstruction. If left untreated the duct may burst, with formation of a salivary fistula.

15. Salivary Fistula is an abnormal opening of the duct of a salivary gland, and may be either internal or external, according as it opens on the inside of the mouth or on the outer surface of the cheek. Such a fistula is due to wounds of the duct, or to a rupture of the duct from suppuration or calculi. The parotid gland is the one most commonly affected. Internal salivary fistula is of comparatively little consequence, as the saliva flows into

the mouth. But in external fistula the flow of saliva on the cheek causes considerable discomfort.

Treatment.—If a calculus is present it must be removed. Then find the internal opening of the duct, and see if it is patent; if it is not patent, an artificial internal fistula must be made; and the edges of the external fistula can be touched with a cautery or pared, and closed with a twisted suture.

16. TONGUE-TIE is practically a congenital shortening of the frænum linguæ. The tongue cannot be protruded beyond the teeth; and suction and, later, articulation are interfered with. The proper treatment is division of the frænum, generally on the notched shield which forms the handle of a grooved director. Care must be taken to avoid wounding the ranine arteries. Blunt-pointed scissors should be used, and the points directed toward the floor of the mouth and away from the under surface of the tongue. Often the frænum is simply nicked with the scissors and the operation completed with the finger nail.

17. PYORRHŒA ALVEOLARIS, or Rigg's disease. In this condition there is found a shrinkage of the gums and alveolar border, together with separation of the gums from the teeth, which become loosened and may fall out. It is due to an inflammatory condition of the gums combined with bacterial infection and an excess of tartar. General cleanliness is indicated, with removal of the tartar; antiseptic and astringent mouth washes and general tonics should also be prescribed. Treatment may have to be continued for a long time as the condition is often intractable; and the patient may expect to lose some of his teeth.

18. ALVEOLAR ABSCESS is the result of inflammation and suppuration in connection with the fang of a carious tooth. It may occur in either jaw. Pus forms in the socket of the tooth and either finds its way out by the side of the tooth or through the gums, in which latter case it is called a gumboil or parulis; occasionally it strips the periosteum from the bone and forms an abscess of large size, and may even produce necrosis of the jaw. The first indications of the trouble are pain and a feeling as if the tooth were a little longer than normal. If the abscess is allowed to remain, there may be severe constitutional symptoms. Incision is indicated, and if it be delayed the tooth becomes loosened and exfoliation of the periosteum with necrosis may occur. In the upper jaw pus from a neglected alveolar abscess may burrow into the antrum of Highmore and set up suppuration there, or it may discharge by way of the nose. In the lower jaw the pus may travel downward and point and burst in the neck.

Treatment consists in disinfection of the mouth, incision of the gum, and extraction of the tooth. As a prophylactic, children should be taught to use a tooth-brush, and their teeth should be regularly attended to by a competent dentist.

19. EPULIS.—This term is applied to a tumor growing from the fibrous tissue of the gum or from the alveolar periosteum. The name is derived from *ἐπὶ* and *τὸ οὖλον*, and means literally a tumor situated "on the gum." There are two varieties: the simple or fibromatous, and the malignant or myeloid. They generally attack the lower jaw.

Simple or fibromatous epulis appears as a rounded, smooth mass, sometimes lobulated or sessile; it is firm or elastic to the touch, and of a color varying from pinkish to deep red. It is generally due to carious teeth and is more apt to be formed on the outer border of the gums, though it may appear between two teeth, causing more or less displacement, and also on the inner surface of the gum. It is covered with epithelium, and may contain a few spicules of bone derived from the maxilla. The presence of the latter is much more common in the malignant or myeloid variety.

Treatment consists in the free removal of the tumor together with any teeth, stumps, or bone that may appear to have some causal relation to the growth. It is well, therefore, to extract a tooth on each side of the epulis, to cut through the whole thickness of each alveolus vertically with a small saw, and then finally to join these incisions at their lower ends by a horizontal incision made with a chisel. Thus the continuity of the jaw will remain notwithstanding the fact that a quadrangular piece of bone has been removed.

Malignant or Myeloid Epulis.—This is really a myeloid sarcoma and springs from the alveolar process. The chief distinction between these two varieties is pathological; the clinical picture being much the same as in the simple variety, except that the mucous membrane covering the tumor is more apt to ulcerate, and there is always a connection with the underlying bone. The treatment, too, is the same, only the malignant variety sometimes requires very energetic and radical treatment.

20. WOUNDS AND INJURIES OF THE MOUTH have, for the most part, the same features as are presented in wounds and injuries elsewhere. The blood supply of the mouth being particularly abundant, there is apt to be profuse hemorrhage, but this same abundant blood supply causes the processes of repair and healing to be very rapid. Hemorrhage from the mouth is due to wounds, injuries, purpura, biting the tongue, plethora, scurvy, and the hemorrhagic diathesis; it is best controlled by the application of cold or pressure. In slight cuts of the lips a little cotton soaked in collodium makes a good protective and also stops the bleeding. In wounds of the mouth we must remember that the buccal cavity always contains bacteria capable of producing infection, and therefore asepsis is not attainable; but antiseptic mouth washes should be used as frequently as possible.

21. BURNS AND SCALDS OF THE MOUTH.—These are generally caused by accident, and are due to hot liquids introduced into the mouth, to chemicals (acids and alkalies), or to inhalation of hot air or steam. They are most commonly met with in children, owing to their greater liability to drink out of the spout of a kettle or teapot. Adults are more likely to suffer in explosions, under which circumstances they may inhale steam or ignited gas. The inside of the mouth and pharynx are involved, and œdema of the glottis is a probable complication. The symptoms are intense burning pain, dyspnœa, suffocating cough; the lips and mucous membrane of the mouth are either white, sodden, puffy, and blistered, or the mouth may escape and show little or nothing of the hurt. In this latter event the glottis may be scalded, when the edges of the epiglottis will be scorched and the larynx also involved.

Treatment is the same as that for burns in other parts of the body: (1) *constitutional*, to combat shock and to keep up the patient's strength; and (2) *local*, in the form of mild antiseptic mouth washes and cool mucilaginous drinks. For œdema of the glottis tracheotomy may be required. There may be cicatricial contractions resulting in great deformity, and, for the relief of this deformity, extensive plastic operations are often performed.

22. ERRORS OF DEVELOPMENT.—The chief of these are harelip and cleft palate, both of which are considered in other parts of the REFERENCE HANDBOOK. Among the other defects, of which mention may be made here, are the following:

Astomia, or absence of the mouth; this, of course, is incompatible with life.

Atresia oris differs from the above in that there is a buccal cavity, but no external opening. This defect is generally combined with other errors of development. The line of the closure is more or less apparent, and the membrane may be thin or tough and dense. As in similar conditions elsewhere incision is required, but care must be taken lest the freshened edges grow together again.

Microstomia, or congenitally small mouth, is a milder form of atresia oris, and is due to the fact that the parts that form the lips have fused to a greater extent than normal, thus causing stenosis of the buccal orifice. The mouth may be so small that the infant cannot nurse. In such a case it must be enlarged sufficiently and the mucous and cutaneous borders stitched together.

Macrostomia, or congenitally large mouth, is genely unilateral, and is said to occur more frequently in nales. It is found in connection with other develop- ntal errors, and is usually due to the non-union of the ndibular and maxillary processes, or to the persistence the lachrymal fissure. The treatment consists in par- and uniting the edges of the cleft sufficiently to re- e the mouth to normal dimensions.

R. J. E. Scott.

reparing this article use has been made of the following: The rmer edition of the REFERENCE HANDBOOK; Ziemssen's yclopædia"; Reynolds' "System of Medicine"; Pepper's "Sys- m of Medicine"; Allbutt's "System of Medicine"; Keating's yclopædia of the Diseases of Children"; Thompson's "Practical dicine."

IULTIPLE (CEREBRO-SPINAL) SCLEROSIS.—(Syn- ms: Disseminated sclerosis; Insular sclerosis.)

EFINITION.—This disease may present manifold ptoms, the most common of which are paresis, with cular rigidity and exaggerated tendon reflexes as in tic paralysis, tremor brought on by voluntary move- ts, nystagmus, scanning speech, amblyopia, apoplec- m attacks, and impaired intellect. The anatomical s of the disease consists of disseminated patches of osed tissue in various parts of the central and per- ral nervous systems.

rIOLOGY.—An hereditary influence has been traced in v instances. Charcot states that the disease occurs frequently in females, but a number of other ob- rs do not concur with him in this view. It occurs frequently between the ages of fifteen and thirty; sionally in young children; rarely, if at all, after r.

aumatic influences, such as blows on the head, con- on of the whole body, exposure, hardship, over- , and profound emotional disturbance, may all be ioned as occasional exciting causes. In a number stances the disease developed after the existence of ute disease, typhoid fever, variola, etc.

MPTOMS.—The area of diseased tissue may be located y part of the nervous system and there may be quite mber of affected areas. Furthermore, the disease be of various degrees of severity, and the symptoms, are but the expression of the locality and intensity disease, may make the most varied clinical pictures. may be an entire absence of symptoms of disease e nervous system, although nodules of sclerosed tissue are found post mortem; or the disease may ate various different organic or functional nervous es. But, nevertheless, the sclerosis seems to have ilection for certain parts of the nervous system, e find, accordingly, in many cases similar, and al- characteristic, clinical manifestations.

erebral and a spinal form of multiple sclerosis are imes spoken of, but usually both brain and cord e involved in the disease, though it may have been t in the one some time before it developed in the Generally the spinal cord is first affected.

disease usually begins very insidiously and is slow progress; in rare instances it has an abrupt begin- perhaps is ushered in by an apoplectiform attack. arliest symptoms may be of cerebral origin, such dache, vertigo, ataxic gait, and slight psychic dis- ces; or there may be a slight tremor in one or both ; but more frequently the symptoms are those of paralysis.

irst there is weakness of one leg, then of both, at- by some difficulty in walking. Gradually, with ing paresis of the limbs, there appear muscular y, especially brought on by active or passive move- exaggerated tendon reflexes, spastic gait, and, rigid contractures of the limbs. The paresis, a less extent, the muscular rigidity, etc., at a later affect the upper extremities, and to these is sub- tly added another motor symptom—one of the rominent and characteristic of this disease—the d intention tremor, *i.e.*, tremor during the per- ce of a voluntary act. Before it is otherwise noticeable, it may be observed in the handwriting or other delicate movements of the fingers, especially if the act is slowly performed. The writing, if carefully observed, will be seen to be full of small indentations which occur with great regularity, indicating that the tremor is rhythmical. When the tremor is well marked any voluntary movement will cause it to appear, and it may be seen to some extent during rest. A common method of eliciting the symptom is to ask the patient to put a glass of water to his lips. The tremor increases and the oscillations of the hand are greater as the latter approaches the mouth. The trembling may become so violent that all the water is thrown out of the glass. When the patient is sitting quietly either there is no tremor, or slight movements of the head and trunk may be observed. If he now perform a voluntary act, as lifting an arm, the tremor in the head and trunk increases at the same time that there is tremor of the acting member. When he attempts to walk there may be such violent tremor of the limbs and trunk as to make walking, or even standing, almost impossible. On the other hand, when the patient lies down and every part is well supported no tremor appears. None is observed during sleep. It is increased by emotional excitement.

All the voluntary muscles may be thus affected, the head as well as the trunk and limbs. Tremor in the face is less commonly seen, though there may be irregular movements, choreic in character.

The distinctive features of the tremor are that it is rhythmical, and that it occurs only with muscular efforts. A very few cases have been reported in which it continued even in rest, but such cases are exceedingly rare. The tremor is not found in all cases. It probably depends on the locality of the disease. It also disappears in any part when the latter has become completely paralyzed.

The tremor can usually be easily distinguished from that of other diseases. In paralysis agitans, in the beginning (and it is only then that the two diseases could easily be confounded), only a few fingers are affected, and the oscillations are fine and very rapid. At the same time the tremor has somewhat the character of coordinated movements. Thus the movement of the thumb upon the fingers has been likened to that of counting money, rolling pills, etc. The tremor of multiple sclerosis is large and coarse, with no appearance of coordinated action. In paralysis agitans, furthermore, the tremor is, to some extent, controlled by voluntary movement, and increases with rest, and the head is very rarely affected. When the tremor is violent it may have the appearance of the movements of chorea. But the latter occur during repose as well as during volitional acts, and they cause an intended movement to be made very irregularly; on the other hand, in multiple sclerosis the general direction of any movement is maintained, but the line of movement is an undulating one, the undulations playing equally up and down along the central line of direction.

The next two symptoms seem to be similar in character to the tremor. The first is nystagmus, a very common symptom, and of value in diagnosis. When not otherwise noticeable, it may be made manifest by movements of the eyes, strong convergence, or forced movements in some direction. The other symptom is scanning speech. Other changes of speech are sometimes present, but this is the most common and most characteristic, and, therefore, of high diagnostic value. The speech is slow and dragging, each syllable being pronounced separately as in the slow scanning of verse, and, therefore, termed scanning speech. If the patient attempts to speak more rapidly, his words are likely to be so jumbled together as not to be at all understood. The voice is monotonous to the highest degree. There is often tremor of the lips at the same time, and, on laryngoscopic examination, there has been found to be diminished tension of the vocal cords.

Other ocular symptoms besides nystagmus are frequently found. Double vision, due to paralysis of some of the external muscles of the eye, occurs, just as in locomotor ataxia, either as a transient symptom at an early period of the disease, or as a permanent condition at a later stage. Amblyopia is also a common symptom. Generally there is only impaired vision, not complete blindness. The ophthalmoscope reveals, in these cases, a discoloration of the discs, due to a degree of atrophy of the optic nerves.

Headache and vertigo are often present, both in the early and in the later stages of the disease. The vertigo often occurs in paroxysms. Occasionally it is due to the double vision, but more frequently it is quite independent of the latter condition.

The mental symptoms often play an important rôle. Sight psychic symptoms may be manifested in the beginning of the disease if the latter first affects the brain, but the graver symptoms are, usually, late manifestations. Change in disposition, irritability, loss of self-control, a tendency to laughing and crying, are common conditions. A certain impairment of intellect—weakened memory, a degree of apathy, etc.—is also not uncommon. But a high degree of dementia is rare. It is likely to occur only when the disease begins at an early age and there is arrested development of the brain, or when the pathological process is very acute. Different forms of insanity are sometimes observed, most frequently melancholia, occasionally delusional insanity.

Apoplectiform seizures, like those seen in general paralysis, are important symptoms. They occur, according to Charcot, in one-fifth of all cases. After slight prodromal symptoms, headaches, etc., coma develops within a few hours, the temperature rapidly rises, often reaching 104° or 105° F., and at the same time the face is flushed and the pulse rapid. Hemiplegia, with flaccidity of the paralyzed muscles, is soon observed. Within a day or two consciousness returns, the temperature falls, and, within a comparatively brief period, the paralysis disappears. Such attacks may occur every few months, or very rarely. They usually leave the patient in a permanently worse condition, thus marking the progress of the disease. Sometimes the patient dies in the attack. These seizures are very much like those of apoplexy, but post-mortem examinations reveal no anatomical basis for them.

In the foregoing have been given the most common symptoms of multiple sclerosis, those found in the majority of cases. But, on account of the distribution of the diseased areas, various other symptoms may be manifested. Thus the disease may attack the posterior columns of the cord, and ataxia, pain, anæsthesia, paræsthesia, etc., will be present; or it may involve the gray matter, when atrophy and paralysis of muscles will ensue. Or the disease may involve the whole thickness of the cord and produce the symptoms of transverse myelitis. When the posterior as well as the antero-lateral columns are affected, many of the appearances of spastic paralysis are likely to be absent, especially the exaggerated tendon reflexes. Symptoms referable to the bladder and to the rectal and genital functions are also likely to appear. If the disease involve the nuclei of the facial, hypoglossal, and pneumogastric nerves, the ordinary symptoms of labio-glosso-laryngeal paralysis will be manifested, and various local cerebral symptoms may appear, according to the location of the foci of disease.

The course of the disease is a very chronic one. Charcot has divided it into three stages—a division applicable to those cases which present the common clinical picture.

The first stage is from the beginning of the disease to the period of complete disability from paralysis and contractures of the limbs. This stage may last for from two to six years or longer. The symptoms are very slow in their progress. They begin as spinal or cerebral, but both sets of symptoms appear before this stage is terminated. There is often an arrest of the symptoms, or even improvement, which indefinitely prolongs this stage, and may give rise to delusive hopes of complete restoration to health.

The second stage, that of the fully developed disease, may last also for from two to six years. There seems to be little change in the patient during this period, and, though entirely helpless, he seems not to suffer in general health.

The third stage is that of decline. The general health is affected, there are loss of appetite, wasting, etc. Cystitis, decubitus, pyæmia, etc., may hasten the end. Or the latter may be due to an increase in the bulbar symptoms, or to an apoplectiform attack. More frequently a fatal termination is caused by an intercurrent affection—pneumonia, typhoid fever, or, above all, phthisis.

The average length of the disease is from six to eight years. In rare cases it terminates in a year or two; occasionally it lasts twenty years.

Morbid Anatomy.—The pathological changes can usually be seen by the naked eye. They consist of numerous patches or nodules of sclerosed tissue scattered throughout the nervous system. The nodules vary in size from merely microscopical proportions to an object as large as a chestnut or larger; they are rounded or irregular in shape, and may often be seen on the surface as slight prominences or depressions, but are found in larger number when sections of the brain and cord are made. Their color is mostly of a gray or reddish-gray; they are translucent, and have a firm, often cartilaginous, consistence. Many of the nodules are of the same color as the surrounding tissue, and are only distinguished by their consistence. In rare instances a few may be softer than the normal tissue, probably indicating recent disease; most of the nodules, on the other hand, are firmer than the normal tissue, doubtless being of very old standing, for such cases come to the post-mortem table only after the disease has existed a long time. The nodules seem to be quite distinctly circumscribed, but the microscope reveals the fact that they merge imperceptibly into the healthy tissue. They are also quite distinct, as a rule, though occasionally they blend into one another. In rare instances there has been found, in both the brain and the spinal cord, a diffuse sclerosis which, to some extent, has united the scattered nodules. On the other hand, secondary degeneration seems rarely, if at all, to develop from the disseminated disease.

The number of nodules found in a single instance may be very small, or may run into hundreds. Their distribution in the cord is very irregular. In some sections they may be found in the anterior, in others in the posterior, columns; in still others in the gray matter, or they may involve all these parts in the same section. Usually a large number of nodules are found in the medulla, pons, and crura cerebri. It is very rare that these parts are found free from disease. In the hemispheres the walls of the ventricles, corpus callosum, and centrum ovale are favored seats of the disease. In the latter two localities the nodules are often quite large. Usually nodules are also found in the large ganglia, while the cortex generally escapes. But few nodules are, as a rule, found in the cerebellum, and these in the central white matter. Similar nodules may be found in the nerves, most frequently in the optic nerves, but occasionally in the hypoglossal, the nerves of the eye, and the roots of the spinal nerves.

The microscopical appearances are those of interstitial myelitis. The nodules are mostly new connective tissue composed of very fine wavy fibrillæ. But in this new tissue the axis cylinders of the nerve fibres can usually be found in large numbers, though their medullary sheaths have disappeared. This is especially true of the nodules in the spinal cord.

At one of the meetings of the Society of German Naturalists and Physicians, Adamkiewicz expressed the opinion that the disease is not interstitial, but develops primarily in the nervous tissue, beginning in the medullary sheaths of the nerves. He bases his opinion upon results obtained by a new method of staining the nervous tissue. His view is altogether at variance with that formerly held, and may be looked upon with doubt, at least until further corroboration is forthcoming.

Morbid Physiology.—Many of the symptoms are easily explained by the lesions found: psychic symptoms by disease of the hemispheres, bulbar symptoms by lesions of the medulla, muscular atrophy by lesions in the anterior cornua, anæsthesia and ataxia by disease of the posterior columns, spastic paralysis by disease of the antero-lateral columns—in some instances cerebral lesions may produce the same symptoms,—while amblyopia and some other symptoms are often due to nodules in the nerves themselves.

The long retention of the axis cylinders accounts for the usual presence of paresis rather than paralysis, for the anæsthesia being slight, for the amblyopia rarely advancing to complete blindness, etc. (In locomotor ataxia there are also numerous axis cylinders in the sclerosed area, and the symptoms usually point to only a partial loss of function.) Charcot attributes the tremor to the same condition. He supposes that the axis cylinders continue to carry voluntary impulses, but, because they are bared of their medullary sheaths, they carry them in an irregular, jerking manner, and hence the oscillations in the voluntary movements. While this must be considered a mere theory, we can speak with more positiveness of the location of the lesion as a cause of the tremor. It seems to be due to nodules in the medulla and pons, or, at least, in the basilar portions of the brain. In a few cases, in which the disease was limited to the cord, no tremor was observed. On the other hand, when tremor was observed during life nodules were always found in the medulla and pons; when it was not observed, these parts were not affected to any extent.

With a considerable degree of doubt, we may attribute the nystagmus to lesions in the corpora quadrigemina, the scanning speech to lesions in the medulla, the vertigo to lesions in the medulla or cerebellum. A satisfactory explanation of the apoplectiform attacks has not yet been given.

DIAGNOSIS.—In some instances a diagnosis is made with the greatest ease, in others it is almost impossible to make a diagnosis. The most common clinical picture—paresis of the extremities with exaggerated tendon reflexes, intention tremor, nystagmus, scanning speech, amblyopia, etc.—is so characteristic that it cannot be mistaken.* But some of the most characteristic symptoms may be wanting, and then the diagnosis is much more difficult. In this case the indications of multiplicity of lesions and the very chronic course of the malady must be the guides to diagnosis. When the disease is limited to the spinal cord one can scarcely do more than guess in distinguishing it from other forms of myelitis. In such cases one must be on the lookout for cerebral symptoms. Optic atrophy is often a valuable diagnostic symptom, not only in this instance, but in excluding hysteria or other functional diseases which may simulate multiple sclerosis.

When the sclerosis affects only the brain it may present some of the manifestations of brain tumor. Here, too, the indications of a multiple lesion and the very slow course of the disease may clear up the diagnosis. But there is another important distinction, in that brain tumors produce to a large extent general symptoms, those of intracranial pressure, such as severe headache, convulsions, and double optic neuritis; while sclerosis produces merely local symptoms, those indicating the loss of function of the part affected by the disease.

The tremor of alcohol, lead, and mercurial poisoning might be mistaken for this disease, but concomitant symptoms and the history of a cause will establish the diagnosis. The tremor of paralysis agitans, with which this disease was formerly confounded, is easily distinguished by the appearance of the tremor, its being controlled to some extent by voluntary effort and increased during rest, and its very rarely affecting the muscles of the head and neck. Furthermore, paralysis agitans is rarely found in persons under forty years of age, while multiple sclerosis rarely occurs after thirty, and, apart from the tremor, the symptoms of the two diseases are quite different.

PROGNOSIS.—Charcot believes that the disease may sometimes be cured, but the opposite view is generally entertained, though its arrest and even improvement for a number of years have been observed. It usually runs a very protracted course. When at its inception it manifests itself in various parts of the nervous system at the same time, it is likely to run a more rapid course. The occurrence of apoplectiform seizures, cystitis, bulbar symptoms, etc., indicates the approach of a fatal termination.

TREATMENT.—The same treatment is applicable as in other forms of chronic myelitis. (See *Spinal-Cord Diseases* in Vol. VII.)

Philip Zenner.

NERVI.—The town of Nervi stands upon a narrow, shelf-like plateau which intervenes between the base of an outlying spur or side range of the Apennines and the shore of the Mediterranean Sea, at a point some six miles distant from Genoa, in a southeasterly direction. The general trend of the coast line along what is known as the Riviera di Levante, or Eastern Riviera, between Genoa and Spezia, is from northwest to southeast; but, as in the case of the Western Riviera, the regularity of the line is frequently interrupted by the occurrence of bays, which are guarded by rocky headlands, jutting into the sea from the main chain of the Apennines, just as similar headlands along the Western Riviera reach down to the sea from the Maritime Alps. The scenery along this coast is consequently very similar to that of the Western Riviera, and, as the writer can testify from personal experience, it is exceedingly picturesque and beautiful. The width of the little plateau upon which Nervi is built does not exceed a quarter of a mile; its elevation above sea-level is very inconsiderable, and probably does not exceed one hundred feet. The shore line at Nervi runs nearly due east and west; the spur or side chain of the Apennines already mentioned, consisting of three separate mountain peaks, extends parallel with the shore, immediately back of the town. The most westerly and terminal peak of this side range is only about seven hundred or eight hundred feet high, and it is covered to its top with a growth of olive trees; the other two peaks are much higher (about twenty-five hundred feet), and their summits consist of bare rock.

The town of Nervi has a population of a little over three thousand, and it is built, in the straggling fashion so familiar to travellers who have visited the Italian coasts, along the old Genoa and Spezia post road. At this point the road does not skirt the shore, but hugs the base of the hills, so that the town stands close under the shelter of their steep slope, and is effectually protected from northerly winds. From easterly winds it is, in common with all points along the Eastern Riviera, protected in great measure by the main chain of the Apennines. The northeast wind is not effectually kept out, but gains access through gaps in the hills, and is sometimes strongly felt at Nervi. "The northwest wind," says Dr. Sparks, "is also not unknown, and Dr. Thilenius says of it, 'The most dangerous wind and the wind which is always the most violent, is the cold, cutting, dry, and bitter northwest.'" The warm, damp, relaxing "scirocco" wind, blowing from the southeast, is also of frequent occurrence.

The rainfall at Nervi is heavier than along the Western Riviera. The average fall in each of the six colder months of the year, derived from seven years of observation, is quoted by Dr. Sparks from Dr. Thilenius as follows: November, 6 inches; December, 4.88 inches; January, 4.78 inches; February, 3.23 inches; March, 4.49 inches; April, 2.20 inches. In the winter of 1876-77 the number of rainy days, including days on which slight showers occurred, during the months of December, January, February, and March, was 48. At Mentone, during the same period, 27 such days occurred (Sparks). This season is spoken of by Dr. Sparks as a comparatively dry one. The winter of 1874–75, on the other hand, appears to have been at Nervi an exceptionally wet one, for Dr. Sparks quotes Dr. Thilenius to the effect that during that season "it rained almost incessantly for three months, day and night, and the air was so saturated with moisture that there was scarcely any difference between the wet- and dry-bulb thermometers." In the comparatively dry seasons of 1875–76 and 1876–77 the mean relative humidity, measured by August's psychrometer, and quoted by Dr. Sparks from Dr. H. J. Thomas, of Baden-Weiler, was as follows:

---

* Schuler reported a case of tumor of the right hemisphere, in the neighborhood of the island of Reil, which produced the typical clinical picture of multiple sclerosis, and Westphal reported two cases with similar histories, in which no pathological changes were found post mortem. But these are such rare occurrences as not materially to impair the diagnostic value of this clinical picture.

	Dec.	Jan.	Feb.	March.	April.
1875–76	64.0	60.0	64.8	66.7	72.7
1876–77	75.0	63.2	61.4	68.5	....

Dr. Kisch[3] gives the mean relative humidity of Nervi as 62.9 to 66.6 per cent. So far as these figures go, they appear to indicate greater dryness of the atmosphere at Nervi than exists at Mentone, yet Drs. Weber[2] and Sparks[1] both pronounce the climate of Nervi to be moister than that of Mentone.

At Genoa, which, it will be remembered, is only six miles distant, the mean relative humidity is decidedly less than it is at Mentone, and during the prevalence of northerly winds it falls very low indeed, below twenty per cent.; occasionally as low as eight or nine per cent. On the other hand, when the "scirocco" blows, the air at Genoa becomes very moist. Dr. Hann, in his "Handbuch der Klimatologie," gives the mean relative humidity of Genoa, for the five months November to March, as fifty-seven per cent. Now the free exposure of Nervi to the moisture-laden southerly winds and its shelter against the cold, drying, northerly winds characteristic of the Genoa climate, would no doubt combine to effect a great modification of the mean of humidity at the former place when compared with that of the latter; a modification, namely, in the direction of a higher percentage of saturation. Yet, taking into account the close proximity of Nervi to Genoa, and the relative humidity *figures* for Nervi given in Dr. Sparks' book, it seems not impossible that this writer and Dr. Weber, in pronouncing the Nervi winter climate moister than that of Mentone, have confounded the two factors of rainfall and humidity. The rainfall of Genoa is far greater than it is along the Western Riviera; the mean relative humidity is, on the other hand, very considerably less; and no better example than this feature of the Genoa climate can be adduced in support of what has already been said in the article on *Climate* (first edition), viz., that "The humidity of the atmosphere can by no means be measured by the amount of the rainfall." Probably the variations in the atmospheric humidity at Nervi are much greater in amount and more frequent in occurrence than they are at Mentone. "In spite of its raininess," says Dr. Sparks, "the soil of Nervi —clay slate—is favorable to its rapid drying."

As to the winter temperature of Nervi, it appears to be about the same as that of Mentone. Dr. Kisch[3] tells us that the temperature of the two places is similar in respect to its mean and to its variations. The observations of General Brocchi, during the years 1849-64, give the mean temperatures of November and December for thirteen years, and those of January, February, March, and April for fourteen years; they are quoted by Dr. Sparks[1] as follows: November, 55.31°; December, 47.84°; January, 46.36°; February, 47.8°; March, 49°; April, 58.1°. The absolute reliability of these figures is not vouched for by Dr. Sparks, as he explains that he "knows nothing of the arrangement of the instruments or hours of reading."

The following table, showing a comparison of the Nervi and Mentone temperatures for a single winter, is quoted from Dr. Sparks' book, its figures being derived from calculations by Dr. Sparks, based upon observations published by Herr Schulze, in his work on the health resorts of the Riviera, and of Middle and Lower Italy.[4]

TEMPERATURES AT NERVI AND AT MENTONE, WINTER OF 1874–75. (Sparks.)

	Nov.	Dec.	Jan.	Feb.	March.
Mean temperature at 8 A.M.					
Nervi	56.0	52.0	51.0	44.0	49.0
Mentone...........	54.0	48.2	50.5	44.5	49.8
Mean temperature at 2 P.M.					
Nervi	59.5	56.5	58.0	50.3	55.4
Mentone..........................	59.2	53.6	56.0	59.0	57.5
Maximum temperature.					
Nervi	70.5	56.0	66.0	61.0	64.0
Mentone..........................	70.5	64.0	64.0	55.0	66.0
Minimum temperature.					
Nervi	44.0	41.0	44.0	36.0	44.0
Mentone..........................	46.0	42.0	46.0	36.0	48.0

The following data for mean temperature at 8 P.M. and for absolute minimum temperature at Nervi, during the months of December, 1876, and January, February, and March, 1877, are quoted by Dr. Sparks from an article by Dr. H. J. Thomas in the *Berliner klinische Wochenschrift*. The figures for the mean temperature are as follows: December, 51.5°; January, 49.3°; February, 47.2°; March, 47.4° F. The minimum temperature observed was 35.2° on March 2d, 1877. It is worthy of note, in connection with this last-quoted figure, that a minimum temperature of 25.5° was recorded in the "West Bay" of Mentone during this same month. Moreover, if one may judge from a table of monthly highest and lowest temperatures at Mentone which is given by Dr. Sparks in his account of that place, it would appear that this winter season of 1876–77 was not an unusually warm one on the Western Riviera, and that March, 1877, was exceptionally cold; and it is reasonable to infer that such was also the case along the Eastern Riviera. If such was the case, and if Dr. Thomas' observations were made under like conditions with those of Messrs. Freeman and Andrews at Mentone, the greater mildness, or, at least, the greater equability of the Nervi as compared with the Mentone climate would be illustrated, although not accurately measured, by these two figures alone.

On the other hand, Dr. Thomas' 8 P.M. figures, when compared with the daily mean figures of Dr. Brocchi, already quoted, show a decided discrepancy between the two sets of observations, especially if we assume, on the authority of the Mentone figures, that at Nervi the winter of 1876–77 was no warmer than the average.

It is to be regretted that no fuller, more extended, and more accurate observations respecting the various climatic factors of the place have as yet been made and recorded at Nervi. Nevertheless, so far as temperature is concerned, the climate is undoubtedly a mild one, and almost identical in this respect with that of the Western Riviera. As remarked by Dr. Sparks: "In spite of the want of really scientific observations on the climate of Nervi, there is no doubt of the mildness of its climate. The abundant subtropical vegetation, and the growth of standard lemon trees, is a proof of this." The following quotation from an article by Dr. Edward Haughton (London *Lancet*, December 13th, 1884) is interesting as illustrating the agency of mountain shelter in the production of Nervi's mild winter temperature. In February, 1884, this gentleman visited Genoa, Pegli, and Nervi, all on the same day, for the express purpose of making observations on this point. "The result," as he tells us, "was that the wind, which was bitterly cold at Genoa, was much milder at Pegli, especially in the valley behind the town, while it was perfectly calm, and even warm at Nervi, so long as the headlands which protect the place were not rounded by the visitor." The same point is further exemplified in a striking manner, although on a small scale, in what Dr. Sparks tells us concerning a sheltered coast-walk at Nervi itself; and everywhere along this part of the Italian coast we find that shelter from cold wind and exposure to the sun combine in varying degrees to cause marked elevation of temperature, even "in the dead of winter." At Nervi the railway runs between the town and the sea. "Below the rail-ay, and just before the rocky shore takes its deep scent into the sea, a path a few feet wide has been cut ɔng the edge of the rock for the use of the coast ıardsmen, and as it accurately follows the indentations the coast line, and is absolutely protected from the rth by high garden walls, or by part of the rocky pe, or the railway embankment, while it gets all the ıthern sun in its full force, it is naturally an excellent ɔmenade for invalids. Here they can walk or sit, or, hey choose, at certain points descend close to the sea, l enjoy a temperature of 64°–68° F., while in the High eet of Nervi the thermometer at the same time is not her than 43° or 44°. Naturally great care is necessary ɔe provided with plenty of wraps to put on when re- ɔing from the shore to the town."

'f amusements for the invalid there appears to be a ıt dearth at Nervi, and the facilities for the making xcursions in the immediate neighborhood are exceed- y limited. "The neighborhood of Nervi," says Dr. rks, "offers but a limited field for excursions owing ıe nearness and steepness of the high hills at the back ıe town. There is no drive along the shore close to ɾi, though further west the road at some places near- ɾerhangs the sea. . . . For amusements of all kinds, pt rod-fishing, Nervi presents little opportunity."

'here are three first-class hotels at Nervi and various ions. A train runs every quarter of an hour to and Genoa. "The mild but tonic climate of Nervi has ɔme years been attracting every season an increasing ɔer of visitors."[5] English physicians are to be l at Nervi.—*E. O. O.*]

ıcerning the class of invalids who should be recom- ɛd or permitted to pass a winter at Nervi, it is ssible to decide with any degree of precision until a r and more thorough series of meteorological obser- ıs shall have given us a more accurate knowledge local climatic peculiarities. For the present it can ɔe said that the general features of the climate are of the Italian Riviera, and that the local modifica- ıre such as render the climate less exciting than that Western Riviera resorts. *Huntington Richards.*

RENTERIC CANALS.—It is now known that dur- very early stages of the development of many ates there is an open communication between the ɔr portion of the medullary canal (spinal cord) and ɔdermic or intestinal canal. To this communica- e name of neurenteric canal has been applied. ginal opening of the archenteron is known ılastopore (see Vol. II., p. 4). In mammals, ther amniota, it is represented by the pos- pening to the exterior of the notochordal It has now been observed in various ver- that as the neural ridges or medullary levelop backward they terminate against ı of the blastopore, which acquires an elon- ɔrm. By their further growth the medul- tes close over across the long blastopore, a manner as to divide it into an anterior ınd a posterior portion. The posterior portion permanently open in certain amphibia and thus to the anus, or it may close over (Fig. 5159, *bl.*, equently open, thus giving rise indirectly to the he anterior portion is an opening enclosed within ullary plate or groove, and may remain open r the groove has closed to form a canal (Figs. 0, *ne*), the true neurenteric canal, which estab- lirect communication between the neural and al tubes. It has been observed in man (Fig. *c*). It might with propriety be termed the Kowalewsky, from its discoverer. Kowalewsky first found it in amphioxus, and subsequently demonstrated its occurrence in various fish types.

The canal lies in front of the true or secondary blastopore and traverses the notochord. According to Durham,[4] it can be well seen in longitudinal sections of early stages of the frog (Fig. 5159) as a short canal, *ne.*, opening widely into the entodermal cavity. Compare also Götte's[1a] description of the neurenteric canal in Bombinator. It was discovered by Gasser[6] in goose embryos. Braun[3] has shown that both canals may be present in various bird embryos at a stage when there are six or eight pairs of myotomes and the development of the tail is just beginning. The neurenteric canal lies a short distance in front of the blastoporic, which is the larger of the two. The two canals appear in some species at the same time, or in other species at slightly different stages. The posterior canal is more often obliterated in birds than the anterior. In the duck and in Motacilla flava the canals are separated both in the times and positions of their occurrence; in the Australian paroquet they are both present contemporaneously, although the neurenteric passage becomes open earliest. Fig. 5160 represents a transverse section, which passes through the neurenteric canal of the paroquet. In the common fowl the blastoporic canal appears not to be open at any period after the formation of the primitive streak.

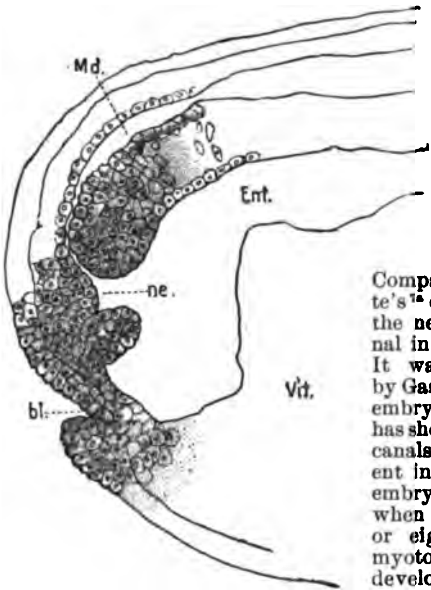

FIG. 5159.—Longitudinal Section of a Frog's Ovum shortly after the Closure of the Medullary Groove. The blastoporic canal, *bl.*, is only partially cut, but was found open in neighboring sections. (After Durham.) *Md.*, Medullary canal; *bl.*, blastopore; *Vit.*, yolk forming the floor of the entodermic cavity, *Ent.*; *ne.*, neurenteric canal.

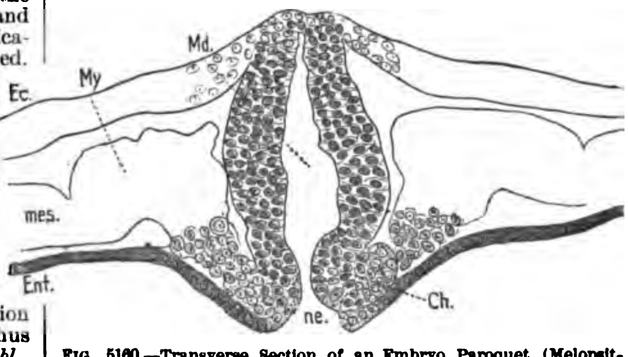

FIG. 5160.—Transverse Section of an Embryo Paroquet (Melopsittacus) to show the Anterior or True Neurenteric Canal. *Ec.*, Ectoderm; *My.*, myotome; *Md.*, medullary canal; *Ch.*, notochord pierced by the short neurenteric canal, *ne.*; *Ent.*, entoderm; *mes.*, mesoderm. (After Max Braun.)

Another canal, which was first satisfactorily described by Braun,[3] occurs in older embryos. The "Enddarm" of Gasser and Kölliker becomes the "Schwanzdarm" (post-anal gut, Balfour[1]) of older embryos, which soon becomes divided, at least in birds, into a dilated terminal portion and a narrower neck communicating with the intestine proper. The posterior section then subdivides, and its narrow end segment lengthens out and unites with the spinal cord. This canal we may designate as Braun's canal. It is not improbable that it is homologous with the amnio-allantoic canal of Gasser,[7] which Rauber[12] has nicknamed the Cochin China canal, after the breed of hens in which it seems most constant. In the one case we may suppose the canal to open after, in the other before, the closure of the posterior end of the medullary groove. If the homology is correct it may be further said that the canal is identical with Kupffer's myelo-allantoidean canal; it cannot be brought into relation with the development of the allantois, as believed by Kupffer,[10] as the allantois and Enddarm are both formed before the canal appears.

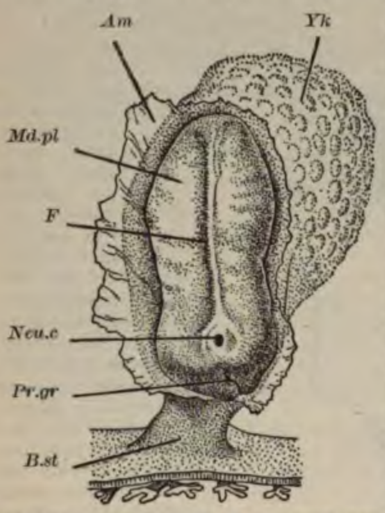

FIG. 5161.—Reconstruction of a Human Embryo 1.54 mm. Long. The amnion has been opened to show the dorsal surface of the embryo. *Yk*, Yolk sac; *Am*, amnion; *Md.pl*, medullary plate; *F*, dorsal furrow; *Neu.c*, neurenteric canal; *Pr.gr*, primitive groove; *B.st*, body stalk. (After Count Spee.) (From Minot's "Embryology," Blakiston, Phila., 1903.)

The significance of the three canals is obscure. The middle one seems unquestionably the temporarily open secondary blastopore. The first, or Gasserian canal, is distinct from the blastoporic, as the two coexist, and it seems desirable that this canal alone should be called *neurenteric*. As to its origin or significance nothing definite can be said, but it may be suggested that it was the excretory opening of the central canal of the spinal cord and that the cilia of the canal served to expel the fluid (compare Balfour[1, 2]). This may have been the condition in the earliest vertebrates, and the neurenteric canal now persists as a rudimentary organ. As to the morphological or physiological interpretation of the third or Braun's canal no satisfactory suggestion has been made.

It seems not impossible that a persistent neurenteric canal may occur as an excessively rare anomaly in the adult.

Charles Sedgwick Minot.

LITERATURE.

The literature of the neurenteric canals is all comparatively recent, and is, for the most part, included in essays dealing with other embryological subjects. Great confusion has arisen from the failure to distinguish the several canals. The reader will find his way most readily by consulting first the text-books of Balfour,[2],[5]; second, the article of Braun,[3]; and third, Rauber's note,[12] although Rauber's terminology is eccentric and perplexing.

PERITONITIS.—(Peritonæitis, Inflammatio peritonei.) The peritoneum is a thin membrane of connective tissue extremely rich in blood-vessels and lymphatics, and is covered by a single layer of flattened endothelial (mesothelial) cells (often called epithelial). These cells are chiefly polygonal, but the cell outlines are often very irregular, serrate, or wavy. By treatment with silver nitrate or by *intra vitam* staining with methylene blue, the cement lines between the cells can be made out; and by especial methods of technique the so-called intercellular protoplasmic bridges connecting the cells may be demonstrated. The connective-tissue layer consists of an interlacing network of fibrous connective-tissue bundles, numerous elastic fibres, and connective-tissue cells. Through this there runs a very abundant capillary and lymphatic network having a free anastomosis. The majority of writers hold that the lymphatics communicate directly with the peritoneal cavity by means of small openings between the mesothelial cells, known as stomata. Some of these writers regard the endothelial lining of the lymph spaces of the peritoneal basement membrane as continuous with the lining of the peritoneal cavity. This is not the case, however, and the mesothelial cells form a probably unbroken layer over both the blood and the lymphatic vessels, the processes of absorption and secretion being carried on through the two layers of cells, endothelial and mesothelial. The absorption capacity of the peritoneal surface is very great, being fully equal, in the case of experiments with certain poisons, to that of direct intravenous injections. Gases, fluids, and even morphological elements may be quickly removed from the peritoneal cavity. On the other hand, the secretory activity of the immense vascular surface of the peritoneum is very great, and in disturbances of the vascular secretion an immense amount of exudate may pass through the peritoneum into the peritoneal cavity. The endothelial and connective-tissue cells of the basement membrane respond very quickly to "irritation" of any kind, and fibroblastic activity is set up more quickly in the peritoneum than anywhere else in the body. The course of peritoneal inflammations is considerably modified by these factors.

The peritoneum lines the entire abdominal cavity, and is reflected over the organs contained within it. Over the organs it forms the serous coat or capsule (*tunica serosa*). The membrane is attached to the underlying parts by a subserous coat of adipose tissue, connective-tissue bands and elastic fibres. Over the organs the subserosa is but slightly developed. The anatomical relations of the peritoneum to the abdominal wall, its investiture of the abdominal organs, the intimate relations of the peritoneal cavity to the female genital tract, etc., in connection with its very vascular structure, peculiarly predispose this membrane to the occurrence of inflammatory processes. Such a predisposition is shown by the fact that peritonitis is one of the most common and important clinical conditions. It is also one of the most serious. The high mortality of acute general peritonitis makes it one of the most dreaded affections. Even in these days of aseptic surgery when so many operative procedures have been divested of their chief dangers, peritonitis still remains to the abdominal sureon and gynecologist one of the complications most eared and most carefully to be avoided.

The occurrence of peritonitis is not dependent upon limatic, seasonal, or meteorological influences. Females e more frequently affected than males, this fact being pendent upon the important rôle which diseases of the male genital tract play in the causation of peritonitis. is therefore seen more often during the years of sexual tivity, but may occur at any age. It is of not infre- ent occurrence in young children. The relation of ritonitis as a complication to many of the acute infec- ns makes its occurrence to a certain degree associated th epidemics of these diseases. Alcohol is regarded a predisposing factor.

ETIOLOGY.—Peritonitis may be *primary* or *secondary*.

rimary peritonitis is, if we except the surgical form, much more rare occurrence than the secondary. It is ally *traumatic*, more rarely, *idiopathic*, *spontaneous*, or *umatic*.

raumatic peritonitis is most commonly due to per- ating wounds of the abdomen. Abdominal injuries hich the wall is not penetrated rarely, if ever, direct- ause peritonitis. Nevertheless, blows, kicks, falls, are often adduced as causes of peritonitis. The e severe the injury, the more likely is the occurrence eritonitis. Hemorrhage into the peritoneal cavity ually followed by inflammation of the peritoneum. wise, trauma may indirectly cause peritonitis through perforation, laceration, tearing, or bruising of the ach or intestines, rupture of the gall bladder, pan- ic duct, urinary bladder, etc., these lesions permit- the entrance of micro-organisms into the peritoneal y. The perforation of the œsophagus or stomach by reless passage of a sound or stomach tube may also ausal factor in the production of peritonitis.

ratire or *surgical* peritonitis may be mentioned in onnection. Before the days of antisepsis and asep- arge proportion of laparotomies were fatal from the nitis following the operation. Even at the present e chief anxiety attending operations involving the neal cavity is the possibility of peritonitis. The mprovement in surgical technique has, however, reduced the number of cases of post-operative itis, and in certain operations in which there is, roper methods, no opportunity for infection the eal cavity is opened with a certain degree of im-

The occurrence of surgical peritonitis is depend- on several factors: the character of the operation possibility of infection during the operative pro- , the amount of damage done to the peritoneal the state of the general resistance of the mem- infection, etc. Surgical peritonitis is due to the ction of bacteria into the peritoneal cavity. But acteria which gain an entrance into the peritoneal et up an inflammation there. It has been shown entally that rather large quantities of bacteria, the pus cocci, may be introduced into the peri- vity of animals without causing peritonitis, the entirely disappearing after a short time. The of a tissue lesion, even though very slight, or ltaneous introduction into the cavity of irritating es, furnishes the conditions requisite for the f the bacteria and for the production of an in- on. The peritoneum therefore when uninjured sess a certain protective power against bacteria. stance is found to be lowered in the case of ge into the cavity, after the removal of ascitic l in cases of pseudomyxoma peritonei. The ndition of the body, conditions of intoxication, etc.. also play a rôle of importance. Fatal may follow the tapping of the abdomen in he small number of bacteria introduced by a septic trocar being sufficient to overcome the esistance. When modern methods of asepsis rly carried out the dangers of surgical peri- relatively slight in all cases in which the con- of the peritoneum with septic material can l. Even when this contamination does occur, the modern procedures of thorough irrigation have greatly reduced the chances of infection.

The existence of a *peritonitis rheumatica* (*refrigeratoria*) has been denied by many writers. While the effects of cold as a factor in the etiology of peritonitis were formerly greatly exaggerated, there can be no doubt, from the large number of observations made by reputable clinicians, that attacks of peritonitis may follow the sudden chilling of the overheated body, prolonged exposure to cold or wet, lying upon the cold damp ground, etc. The effects of such chilling of the body are especially noticeable when the abdominal vessels are overfilled with blood (*physiological congestion*). In women, particularly in girls at the time of puberty, a wetting or chilling of the body at the menstrual period is not infrequently followed by peritonitis. In all of these cases the effect of the refrigeration is not directly to excite the peritonitis, but to render the membrane less resistant to infection. The chilling plays the same rôle here as in the case of the mucous membranes. Diplococci have been demonstrated in the exudate of cases of so-called rheumatic peritonitis; and it is very probable that all such cases are infections following and dependent upon a lessened resistance of the body.

Cases of *idiopathic* or *spontaneous* peritonitis have also been reported clinically.

The autopsy findings in such cases show the presence of an infection proceeding from the female genital tract, the appendix, or some other of the abdominal organs. Such cases occur most frequently in females and in very young persons. In the former the infection is nearly always secondary to some unsuspected condition of the internal genitals. The gonococcus plays an important rôle in such cases, particularly in very young girls. It has been said that the peritonitis apparently arising spontaneously in young girls is usually gonococcal, a gonorrhœal infection of the genital passages existing at the same time. In young male children cases of apparent spontaneous peritonitis are usually found to be due to appendicitis. Further, spontaneous cases of peritonitis have been found at autopsy to be ambulatory typhoid, acute tuberculosis of the peritoneum, etc. On the whole it may be said that the existence of a true idiopathic peritonitis, while probable, has not yet been definitely demonstrated. A *cryptogenic hæmatogenous* infection of the peritoneum is of course possible and certainly occurs in tuberculous peritonitis, but has not yet been shown positively to occur in the case of the pyogenic organisms.

Likewise the existence of a toxic peritonitis, though assumed by some writers, has not been demonstrated. The occurrence of so-called *nephritic* or *uræmic* peritonitis seen in the late stages of Bright's disease is to be regarded as of the nature of a terminal infection, and similar to the pericarditis and pleuritis occurring in the same disease. The occurrence of peritonitis in association with or following various forms of intoxication is to be explained in the same way as the rheumatic—the lessened resistance of the body tissues and the pathological alterations of the body juices predispose to infection.

Since primary inflammations of the pericardium and pleura are of relatively more frequent occurrence, the greater rarity of primary peritonitis may be explained by the assumption that the peritoneum possesses a greater resistance and protective power than the other serous membranes. This relative greater immunity of the peritoneal cavity has been demonstrated experimentally.

SECONDARY PERITONITIS.—It should be noted at this point that various writers upon the subject of peritonitis are not agreed in their conceptions of primary and secondary peritonitis. In a very broad sense the term primary may be applied to those forms of peritonitis which are not secondary to, or do not occur in association with, any other acute or chronic disease, hence not metastatic; and, further, which do not arise by contiguity from any of the organs or structures covered by the peritoneum. Terminal infections should then be classed as secondary rather than as primary. A number of recent hairs, etc.) when aseptic produce a local encapsulating peritonitis. When septic they may excite a diffuse purulent or fibrinous process. Free bodies, such as fat tissue, blood clots, pieces of fibroid tumors, etc., may become calcified or encapsulated, setting up a local adhesive peritonitis. In *extra-uterine pregnancy* hemorrhage into the peritoneal cavity following the rupture of the sac may excite an intense peritoneal irritation even in the absence of infection. In such cases the blood itself must exert a chemical irritation upon the peritoneum, or irritating toxins are contained or developed within it.

Finally, during *intra-uterine injections* irritating substances may be forced through the tubes into the peritoneal cavity and excite a toxic inflammation. Such cases may occasionally be properly classed with the primary forms of peritonitis, but inasmuch as some inflammatory condition of the uterus or tubes is usually present it becomes difficult to say to what extent the injection is alone responsible for the peritonitis.

Parasites.—A number of observers have noted at autopsy the presence, in the peritoneal cavity, of intestinal worms in association with a perforative peritonitis. In some cases the perforation has been regarded as caused by the parasite (usually the common round worm), the peritonitis following the perforation. Some of the reported cases are very doubtful. Katsurado several years ago reported two cases of purulent peritonitis which he regarded as caused by round worms. A very careful examination, both at the time of operation and at the autopsy, failed to reveal any other cause for the peritonitis. In both cases the affection ran a very severe course. Osler and other recent writers accept the view that *Ascaris lumbricoides* may penetrate the intestinal wall and excite peritonitis. The *Amœba coli* has been found in the exudate of peritonitis.

Under rare conditions peritonitis may follow other conditions not mentioned above. As stated before it is hardly feasible to enumerate all the possibilities, but the most common and important sources of secondary peritonitis have been given; and if the extensive anatomical relations of the membrane are borne in mind it will usually not be difficult to trace to its source any secondary peritonitis that may be encountered.

Bacteriology.—Inasmuch as the great majority of cases of peritonitis are caused by bacteria the bacteriology of peritonitis becomes a matter of very great importance. In recent years a number of important investigations have been carried out along this line, but much work yet remains to be done before we shall possess a fully satisfactory knowledge of the subject. It has been demonstrated that very different forms of bacteria may be found in the exudate of peritonitis. In the majority of cases there is a mixed infection, several varieties of pathogenic bacteria being present, or a number of varieties of pathogenic and non-pathogenic bacteria may be found together. According to Tavel and Lanz the hæmatogenous cases of peritonitis are mono-infections, while those arising by contiguity from a neighboring diseased organ are usually poly-infections. It is probable that in some at least of the cases of mono-infection the single variety found may have crowded out other varieties which were originally present. This is particularly likely to have been the case in those instances in which the only micro-organism present is a harmless saprophyte. In those cases in which the exudate is sterile there is also the possibility that the original pathogenic bacteria causing the inflammation have died out.

The pathogenic bacteria most frequently found in peritonitis are the *Streptococcus pyogenes*, *Staphylococcus aureus*, *Staphylococcus albus*, *Bacterium coli commune*, *Diplococcus pneumoniæ*, *Bacillus pyocyaneus*, and the *Gonococcus*. (Tuberculosis of the peritoneum will be considered separately.) Less frequently found are the *Bacillus typhosus*, *Bacillus aërogenes capsulatus*, *Bacillus proteus*, *Bacillus lactis aërogenes*, *Micrococcus tetragenus*, and a number of unidentified pathogenic and non-pathogenic bacteria.

In perforative peritonitis the *Bacillus coli communis* usually predominates; in puerperal peritonitis the chief rôle is played by the *Streptococcus pyogenes;* while in those cases of peritonitis which apparently arise spontaneously the *Pneumococcus* or the *Gonococcus* is the chief exciting factor. In all those cases of peritonitis in which the infection comes from without the flora resembles that of ordinary surgical infections, except for the prominent part played by the colon bacillus. In those cases which arise by contiguity from some one of the neighboring organs the staphylococcus plays a chief rôle, except in the case of intestinal infection in which the colon bacillus alone or combined with the former is usually found.

Much discussion has taken place as to the pathogenic rôle of the colon bacillus in peritonitis. The pyogenic properties of this organism have been quite generally accepted, and there can be no doubt of the existence of a primary colon-bacillus peritonitis. In the majority of cases in which the colon bacillus is found pyogenic cocci are also present, and it is probable that in some of the instances in which this organism alone was found in the exudate it had overgrown the cocci. Barbacci in experimental work upon dogs found that the colon bacillus often outgrew the pyogenic cocci. Infections of the peritoneum with the colon bacillus occur through the bladder and female genital tract as well as directly from the intestine. There are still several questions to be settled before the exact pathogenic value of the colon bacillus can be fixed. Its relations to the pyogenic cocci need to be more definitely determined in regard to the part played by each as primary excitants of inflammation. Further, many of the cases regarded as colon-bacillus infections were diagnosed as such from the results of the bacteriological examination made at autopsy some hours after death. As the colon bacillus may enter the peritoneal cavity after death and increase there, overgrowing other bacteria, it is necessary, in order definitely to determine the relation of this organism to a peritonitis, to make bacteriological examinations of the peritoneal exudate during life.

An effort has been made by a number of writers to make a bacteriological classification of peritonitis. Freund divided all cases of peritonitis into three classes: one due to pyogenic organisms, one to fæcal bacteria, and the third to toxic substances. Bumm distinguished a septic, aseptic, and a specific peritonitis. The septic he divided into a streptococcus peritonitis and a putrid peritonitis, the latter not caused by any one form of bacteria but by a multiple infection. The aseptic peritonitis he regarded as due to mechanical, thermal, or chemical influences alone without bacterial agency. In the class of specific peritonitis he placed tuberculous and gonorrhœal peritonitis. Tavel and Lanz have offered a more complex classification based upon the anatomical origin of the infection, special kinds of peritoneal infection being derived from the stomach and intestine, the gall bladder and liver, the female genital tract, the kidneys, urinary bladder, etc., other forms still being derived from hæmatogenous infections and operations.

Flexner has reported a series of observations upon one hundred and six cases of peritonitis studied from the bacteriological point of view. The material was obtained at autopsy, cover-glass and aërobic cultures being carried out. Few anaërobic cultures were made and the pathogenic properties of the bacteria isolated were tested but rarely. In spite of this incompleteness of the investigation the results are of interest. Twelve of the cases presented the character of a primary peritonitis according to Flexner's definition. In all these cases there was a previous chronic disease. In two cases no micro-organisms were found; in nine cases there was a single infection, and in one case a multiple infection. The *Streptococcus pyogenes* was found five times, four times alone, and once in association with the colon bacillus; the *Staphylococcus aureus* and *albus* twice, the *Micrococcus lanceolatus*, *Bacillus proteus*, *Bacillus pyocyaneus*, and an unidentified bacillus occurred twice each.

The secondary cases Flexner divides into two classes: *exogenous* peritonitis and *endogenous* peritonitis. In the

mer the infection entered from without (wound infec-
n); in the latter the bacteria came in part or wholly
m the intestinal tract. Thirty-four cases of the ex-
enous form were examined. Of these, 25 were mono-
ections, nine were multiple. The following tables are
en from Flexner's article (Philadelphia *Medical Jour-*
, 1898):

CRO-ORGANISMS FOUND IN CASES OF EXOGENOUS PERITONITIS.

	Total number of cases.	Alone.	Combined.
ylococcus aureus	15	12	3
ylococcus albus	3	2	1
tococcus pyogenes	10	5	5

ococcus albus and unidentified organism	1

nparison of the table in the exogenous and en-
forms is of interest. It will be seen that mul-
ctions are relatively more frequent with the
us form, and that the variety of bacteria is
ater. The streptococcus takes the place which
lococcus holds in the exogenous cases and the
llus plays a much more important rôle. The
which the pathogenic staphylococci seem to
dogenous peritonitis is of clinical importance,
as the streptococcic infections may be asso-
metastasis. The infections in the exogenous
nble those of ordinary surgical or traumatic

Basing his conclusions upon the observa-
ner would distinguish three forms of peri-
rimary or idiopathic form restricted to a small
erminal infections; a second variety analogous
to surgical infections; and a third variety dependent upon disease of an intraperitoneal organ, whereby micro-organisms and other extraneous substances gain entrance to the peritoneal cavity, break down its resistance, and lead to infection.

Pneumococcic Peritonitis.—Cases of peritonitis due to the *pneumococcus* have been described by Frommel, Fraenkel, Charrier, Veillon, Beco, Bryant, Comby, Brun, Burckhard, and others. Brun reports fourteen cases of pneumococcus peritonitis in children. The majority of the cases of peritoneal infection with the pneumococcus occur in young girls. The avenue of infection is through the genital tract. The peritonitis may or may not be associated with inflammations of other serous membranes. The infection is frequently localized in the pelvis. The prognosis is favorable in those cases in which the exudate becomes encysted by adhesions, but metastases and localizations of the micro-organism in other parts of the body may occur. The diffuse form is usually fatal. In the case of operative procedures in pneumococcus pyosalpinx the greatest care must be taken to prevent infection of the peritoneum since the peritonitis thus excited is usually very virulent. Pneumococcus peritonitis may also result from extension or perforation in the case of a pneumococcus appendicitis. The relation to pneumonia and arthritis has been mentioned above. It is of importance in the diagnosis of this condition to bear in mind the fact that after death the pneumococci may entirely disappear from the peritoneal exudate, the colon bacillus or some other organism being left. Cases have been reported in which the examination of the pus from the peritoneal cavity during life, or soon after death, showed the presence of pneumococci in great numbers, while examinations made twenty-six to forty-eight hours later showed only the presence of intestinal bacteria.

Gonorrhœal Peritonitis.—The occurrence of an acute general peritonitis caused by the *Gonococcus* is now firmly established, and the condition is probably not infrequent in women affected with gonorrhœa of the internal genitals. Wertheim in opposition to Bumm was the first to maintain that gonococci may multiply within the peritoneal cavity and excite there an inflammation which may spread over the entire peritoneum. An increasing number of such cases is being reported. The view of Bumm and others, that the *Gonococcus* finds no favorable soil upon serous surfaces, and that its growth upon the peritoneum is slight and localized has been completely overthrown by recently reported cases. The infection of the peritoneum with the *Gonococcus* occurs chiefly in women, although cases of gonorrhœal peritonitis in men have been reported by Jadassohn, Horowitz, von Zeissl, and others. In the female the infection usually proceeds from the tubes. In the case of an infection of the woman with very virulent gonococci there may develop suddenly a most severe general peritonitis. The passage into the peritoneal cavity, from the mouth of the tube, of pus rich in gonococci always excites a general peritonitis; if the flow is small, and if but few gonococci are present in the pus, or if these are reduced in virulence a local peritonitis is usually set up. Gonococcic peritonitis is relatively more frequently a complication of gonorrhœal vaginitis and vulvitis in young girls. Such cases are unfortunately not rare in some of our large cities. The belief held by certain of the lower classes that gonorrhœa in the adult may be cured by rubbing the male organ over the external genitals of young girls is probably responsible for some of these cases. The peritoneal affection may appear as a mild or severe acute general peritonitis, or it may run a latent course as a chronic inflammation. The prognosis in these cases is always serious. Recovery may be followed by sterility.

PATHOLOGY.—The pathological changes found in the peritoneum in inflammation of this membrane are essentially the same as those occurring in inflammatory processes of the pleura and pericardium. According to the duration of the inflammation there may be distinguished an *acute*, *subacute*, or *chronic* peritonitis. According to the extent of the membrane involved a peritonitis may be *local* or *circumscribed*, *general* or *diffuse*. A localization of the inflammation in the pelvis is generally spoken of as a *pelvic* peritonitis, in the neighborhood of the appendix as *peri-appendiceal*, over the spleen and liver as *perisplenitis*, *perihepatitis*, etc. According to the nature of the exudate there may be distinguished a *serous*, *fibrinous*, *purulent*, *hemorrhagic*, and a *putrid* or *gangrenous* peritonitis. Besides these pure types a variety of combinations, such as sero-fibrinous, sero-purulent, fibrino-purulent, sero-hemorrhagic, etc., occur.

Within certain limits the anatomical picture presented in all cases of peritonitis is essentially the same, but the appearances seen at autopsy or operation may vary greatly according to the chronicity, severity, and extent of the inflammation, the amount and character of the exudate, etc. The picture of a severe *acute general peritonitis* is, however, very characteristic. The abdomen is distended and tympanitic over the dome and dull over the flanks. When the cavity is opened the distended coils of intestine rise up through the opening, and an escape of gas may take place, even in non-perforative peritonitis. The serous surfaces are cloudy, in slight cases having the appearance of glass which has been breathed upon. Both the parietal peritoneum and the outer surface of the coils may be more or less reddened, injected, or even show ecchymoses. When the coils are lifted up and separated the reddened areas appear to be arranged in bands along the intestine. As a rule these reddened bands correspond to the spaces between the coils at those places at which the sides of the coils do not touch. The vessels of the serosa of these spaces are usually markedly hyperæmic, while at those points at which the coils do touch the vessels are less congested. According to Wilks and Moxon these spaces, which are triangular on cross section, form a system of communicating tubes through which the exudate may spread; and because of the lower resistance over these free surfaces absorption of the exudate is carried on here to a greater extent than elsewhere over the peritoneal surface. The loss of lustre and the cloudiness of the serous surfaces are due partly to the degeneration and desquamation of the endothelium, and partly to a layer of fibrin which is deposited over the surface. The latter may vary greatly in amount; in some cases the fibrin film may be so thin that it can be seen only as a slight cloudiness when examined by oblique light, or it may be made evident by rubbing off the delicate coating with a damp cloth or by scratching the serosa with the edge of the knife. In other cases the serosa may be covered with a thick, grayish, yellowish, yellowish-gray or reddish-gray exudate which may extend over the coils in a sheet, or in strings or bands of varying size, or appear as flakes scattered over the dull, lustreless surface. The fibrin may bind the coils more or less firmly together; in acute cases such adhesions are easily separated by the fingers, but in older cases the adhesions become organized to a greater or less extent, and so firm that they cannot be torn. The spleen and liver may become entirely covered by fibrinous sheets, or tags and flakes of fibrin may be scattered over their capsules. The amount of fibrin may be much greater in some parts of the cavity than in others, and by causing adhesions between neighboring structures may shut off portions of the cavity and confine the fluid exudate to certain regions.

Free fluid is usually present in the dependent portions of the cavity, in the flanks, pelvis, and the pockets between the coils. The amount varies greatly, sometimes many litres (20–40) causing a great distention of the abdomen, while at other times only a small amount is present. The fluid is always more or less cloudy or opaque, but varies in character according to the nature of the exudate, the character of the infection, the occurrence of perforation, etc. It may be serous, purulent, hemorrhagic, fibrinous, putrid, etc. In the great majority of cases it is fibrino-purulent, a pure purulent character rarely occurring, although a purulent character usually predominates. Rarely is it serous or sero-purulent. It is very often putrid (perforative peritonitis), and is then sanious, greenish, or grayish, having a gangrenous odor, and may contain gas bubbles. Except in the case of tuberculosis or carcinoma a hemorrhagic exudate is very rare. The distribution of the exudate is generally very irregular owing to fibrinous adhesions. It usually collects in greatest amounts in the pelvis, flanks, splenic and hepatic regions, and in the deeper parts of the two hypochondriac regions. It often becomes encapsulated by fibrinous adhesions between the coils themselves, or between these and the abdominal wall or some one of the abdominal organs. The omentum often plays an important part in the encapsulation of exudates of small size in the appendix region and in the neighborhood of perforating ulcers of the intestine. Large collections of exudate are often found between the liver and the diaphragm; when of a purulent character and encapsulated from the other portions of the cavity the condition is often spoken of as a *subdiaphragmatic abscess*. Gas is particularly likely to collect in this region. In some cases the liver may be pressed tightly against the diaphragm, its diaphragmatic surface flattened and dry. The exudate often follows along the tubular spaces between the coils, so that the exudate from a pelvic peritonitis may pass under the lower coils of the ileum into the cæcal region and upward along the ascending colon to the right hypochondrium, then along the lesser curvature of the stomach to the cardiac end. In these regions the exudate may collect in large amounts, while elsewhere in the cavity there may be scarcely a trace of peritonitis. Not infrequently the exudate may become completely shut off from the cavity by fibrinous adhesions, which, becoming organized, finally form a fibrous connective-tissue capsule enclosing the exudate, which is either absorbed, organized, or undergoes inspissation or calcification. As mentioned above, the omentum plays an important rôle in such encapsulations, which are most often seen in the neighborhood of the appendix and the female pelvic organs. In the case of a perforative peritonitis the exudate may contain, in addition to the purely inflammatory products, also stomach or intestinal contents, bile, urine, etc.

In the more severe cases the entire intestinal wall may be involved, becoming swollen, œdematous, and easily torn. Even in the light cases the subserosa is œdematously swollen and may be easily stripped off from the muscularis. The muscle coats may be completely paralyzed; hence the occurrence of marked tympanites, general or local. On opening the stomach and intestines the mucosa is usually found to be pale, swollen, and œdematous. Likewise the superficial portions of the liver, spleen, gall bladder, etc., are œdematous and swollen, often appearing as if macerated. The gall bladder and the lower edge of the liver in particular may show an extreme œdema. The tissues of the mesentery are swollen, moist, and more easily torn than normally. The mesenteric and retroperitoneal glands are usually pale, soft, and enlarged. Even the muscles of the abdominal wall may be pale and œdematous, and the parietal peritoneum can be easily stripped from its attachments. The omentum is swollen, injected, and œdematous. It is very frequently rolled up into a thick mass, but in the case of surgical or perforative peritonitis it is usually more or less adherent to the site of injury. It may be covered with a thick layer of fibrin and may aid in the encapsulation of the exudate. The diaphragm is usually pushed up to the third or even second rib; the lungs show partial atelectasis, particularly the lower lobes; and the heart is pushed upward and more or less to one side.

Although the changes just described apply to the great majority of cases of peritonitis, yet the limit of variation is great, in so far as the appearances presented by individual cases are concerned. A pure *serous peritonitis* (*peritonitis serosa*) is relatively infrequent. Some fibrin is almost always present, so that the exudate should be more properly termed sero-fibrinous. The fluid exudate is yellowish, slightly cloudy, and contains but few cells, but fibrin flakes are found floating in it. Over the peritoneum there is usually a delicate film of fibrin. A pure *fibrinous peritonitis* is not common as a general process,

it is often seen as a local peritonitis. The serosa is
udy, dry (*peritonitis sicca*) and covered with sticky
rin.

When the number of cells in the exudate is so great as
cause a turbidity, the peritonitis may be styled *purulent*
ritonitis purulenta). A pure purulent peritonitis is
o rare, the character of the exudate being usually that
a *fibrino-purulent* inflammation. The coils are usually
tened together by masses of fibrin, while in the pockets
ween them a relatively pure purulent exudate is
nd, usually in large amounts (20–30 litres). The so-
led *peritonitis ulcerosa* is a misnomer, the appearances
ulceration over the surfaces of the abdominal organs
the parietal layer of the peritoneum being due to a
of substance through erosion and pressure. In such
s the purulent exudate may perforate into the stom-
intestine, ureter, bladder, uterus, or through the
hragm or abdominal wall (*secondary perforative peri-*
tis). In the last-named case the perforation is usually
ted at the navel. This event happens more frequent-
children than in adults.

the case of *putrid peritonitis* the exudate has a foul
and is irritating to the skin of the operator or prosec-
In color it varies from dirty-green to brownish.
fibrin of the exudate and the serosa itself may be
vise dark-colored. Gas may be present in the cavity,
the odor of hydrogen sulphide is often very pro-
ced even when no perforation has occurred. In the
of a perforation of stomach or intestine food remains
ces may be found in the exudate. Brownish masses
lso sometimes present; on microscopical examina-
they are found to consist of colonies of bacteria.

acute *hemorrhagic peritonitis* is rare. It is usually
iated with carcinoma or tuberculosis, but occurs
in morbus maculosus Werlhofii and in scurvy.
gh the presence of hydrogen sulphide in the exu-
the blood pigment may become converted into a
gen-sulphide compound, giving a gray or slate
to the exudate and serosa (*pseudomelanosis*). Fried-
has described an especial form of hemorrhagic peri-
under the name of *hæmatoma peritonei*. In such
the peritoneal surface is covered with layers of
clot which are becoming organized, the condition
analogous to the subdural hæmatoma.

umscribed peritonitis presents practically the same
rances as the general form, except in being localized
h the rapid formation of firm adhesions which pre-
he inflammation from spreading (*peritonitis adhæ-*
These adhesions may quickly become organized.
scribed peritonitis occurs most often as a
hlitis (peri-appendiceal) dependent upon per-
n of the appendix, and as a pelvic peritonitis
-peritonitis) due to diseased conditions of the ute-
l its appendages. It may be caused also by per-
e processes (ulcer, new growths, etc.) of stomach,
e, gall bladder, etc., by splenic infarction, hepatic
, and other local inflammations of the intraperi-
rgans. The so-called subdiaphragmatic abscess
apsulated purulent peritonitis. Similar encysted
ns of exudate may be found in any part of the
al cavity, but are more frequent in the regions
Gonococcic peritonitis is usually circumscribed
elvis. The part which the omentum plays in the
lation of a local peritonitis has been mentioned
Through its aid many cases of perforation peri-
particularly in the case of the appendix, are
l to a narrow area. The frequency with which
adhesions are formed about the appendix, tubes,
ing ulcers, new growths, etc., is evidence of its
at service in limiting peritonitis.

cations.—The complications of acute peritonitis
y and important. Perforation of the peritoneal
into some viscus or through the abdominal walls
mentioned. Occasionally the pus may break
into two neighboring coils of intestine at the
e, giving rise to the so-called *fistulæ bimucosæ*.
morrhage may follow perforation into an ab-
blood-vessel. Metastasis may occur and a general pyæmia may result. It is not uncommon in the case of a severe acute general peritonitis to find at autopsy a beginning pleuritis, pericarditis, or meningitis. Sometimes all the serous membranes may be equally involved (panserositis). Such pathological findings are seen most frequently in puerperal peritonitis.

Microscopical Appearances.—Sections through an acutely inflamed peritoneum present changes which are analogous to those of inflammations of other serous membranes. The surface of the membrane is covered with a more or less thick layer of fibrin containing a varying number of leucocytes. The latter usually show karyorrhexis, the diffusion of the chromatin throughout the fibrin causing the latter to stain bluish. Beneath the exudate the endothelium is degenerated, necrotic, or desquamated. The connective tissue of the basement membrane is œdematous and infiltrated with leucocytes. The lymphatics are greatly dilated and contain fibrin and large numbers of leucocytes. The blood-vessels are also greatly congested and filled with leucocytes. The endothelial cells of both lymph- and blood-vessels are usually somewhat swollen. Scattered hemorrhages of small size may also be found. The subserosa is usually actively involved, the connective tissue being œdematous and infiltrated with leucocytes; the vessels are congested and small hemorrhages may occur. Fibrin threads may be found in the intercellular spaces of both serosa and subserosa. The muscularis is involved to a much less extent. Its vessels are congested and the intermuscular connective tissue is more or less œdematous and contains an increased number of leucocytes. In severe cases the nerve cells of the intestinal wall may present various changes, such as vacuolation, hydropic degeneration, chromatolysis, etc. In the later stages of the inflammation evidences of proliferation are found in the endothelial cells of the blood- and lymph-vessels and in the connective-tissue cells of the serosa and subserosa. Fibroblasts wander out into the fibrin of the exudate and a new formation of capillaries takes place. Even in attacks of peritonitis lasting but five to seven days the organization of the exudate may have advanced considerably. In the further progress of the disease connective-tissue adhesions and false membranes may be formed, or marked thickenings of the peritoneal surfaces may result. Should complete healing take place the newly formed connective tissue becomes scar-like and hyaline, and marked retractions of the omentum and mesentery may be caused. The remains of old organized fibrinous exudates are most frequently seen in the form of tendinous patches or small pearly nodules over the surface of the spleen, liver, or intestine. Extensive thickening of the pelvic peritoneum may result from the healing of circumscribed peritonitis in this region. During the stage of active fibroblastic proliferation such a large mass of granulation tissue may be formed that in the case of a circumscribed peri-appendiceal peritonitis a tumor may be produced which may be mistaken clinically for a malignant neoplasm, and even when examined microscopically might be mistaken for a sarcoma. Such tumor-like masses may also be found in the omentum. Should healing take place the tumor may gradually contract and finally entirely disappear ("disappearing tumor"). The presence of exudate not yet organized, the large number of polymorphonuclear leucocytes showing karyorrhexis, the hypertrophic character of the endothelium of the numerous capillaries, the presence of many plasma cells and phagocytes, the development in areas of a fibrous intercellular substance, etc., are among the points to be considered in making a microscopical diagnosis of tissue removed from such tumor-like formations.

Subacute Peritonitis.—In cases running a slower course the amount of exudate is usually less than in the acute forms, although in some cases in which it is more serous in character the amount may be very large. The adhesions are firmer, organization having progressed to a greater extent. The serosa is thickened, roughened, and wholly lustreless, and is often grayish or slate-colored. The injection of the blood-vessels is much less, and there is also less œdema of the subserosa. Exacerbations, which are very likely to occur, give the appearances of an acute inflammation. Microscopically the exudate covering the serosa is found to be partly organized, and there is a fibroblastic increase of tissue. The cells of the exudate may show fatty or hydropic degeneration.

Chronic Peritonitis.—Chronic peritonitis may follow an acute process or it may develop insidiously. The changes seen in chronic peritonitis are essentially the same as in the acute process, the chief difference being in the more advanced organization of the exudate with resulting firm adhesions and formation of false membranes, tendinous patches, etc. When numerous adhesions are formed the condition is termed *peritonitis chronica adhæsiva.* The capsule of the liver and spleen may be greatly thickened and hyaline (chronic perihepatitis, chronic perisplenitis). Scar-like thickenings and retractions of the omentum and mesentery may be found (*peritonitis chronica retrahens*), and in the former there may be produced tumor-like masses of granulation tissue. It is usually rolled up above the level of the umbilicus. Marked deformities of the intestine and intraperitoneal organs may be produced by the contraction of the new-formed connective tissue (*peritonitis deformans*). Partial or complete stenosis of the intestine, common duct, ureters, tubes, etc., may result from the contraction or pull of band-like adhesions. Incarceration of portions of the intestinal coils in hernia-like sacs formed by adhesions may also occur. Inasmuch as exacerbations are not infrequently seen in chronic peritonitis the picture of a recent exudation may be added to that of an older process. The *hæmatoma peritonei* of Friedreich mentioned above is associated particularly with a rare form of chronic hemorrhagic peritonitis. Chronic peritonitis may be local or general; the former is the more common. The inflammation may be dry, or a sero-fibrinous exudate may be present; less frequently the exudate is hemorrhagic or purulent.

Local chronic peritonitis is seen most often in the hepatic region (cirrhosis, gall-stones, syphilis, etc.), in the splenic region (perisplenitis), and in the pelvis of the female. In prostitutes a local chronic pelveo-peritonitis is nearly always present in the form of adhesions. The appendix region, the neighborhood of gastric and intestinal ulcers, hernial sacs, etc., are also frequent seats of chronic peritonitis.

Attention has recently been directed to the condition designated "*chronic multiple serositis*" or "*multiple progressive hyaloserositis*" which is characterized by a slowly progressive hyperplasia of the serous membranes with secondary hyaline changes. In the case of the peritoneum the condition is usually most marked over the capsule of the liver or spleen (chronic perihepatitis, chronic perisplenitis). The thickened and hyaline capsule presents an appearance resembling the icing of a cake ("Zuckergussleber" of Curschmann, "iced liver"). An obliterative pericarditis or pleuritis may or may not be coincident with the peritoneal condition. The capsules of the liver and spleen may be involved at the same time or either one may alone show the change, or the condition may be diffuse throughout the entire extent of the peritoneum, or it may occur as a part of a multiple affection of the serous membranes. When affecting chiefly the liver capsule the condition may be the result of a local chronic peritonitis, an acute or subacute hepatitis, chronic mediastinopericarditis, or a chronic obliterative pleuritis. It may also be a part of a Glissonian cirrhosis, perhaps associated with syphilis or tuberculosis. The affection of the splenic capsule is usually the result of a local chronic peritonitis, or is associated with syphilis or tuberculosis. Chronic hyaloserositis is essentially a hyperplastic inflammation, and is probably due to an infection with micro-organisms of a low virulence. In the majority of cases it is probably tuberculous. Microscopically the thickened splenic or hepatic capsule consists of laminated hyaline connective tissue, usually poor in cells, but occasionally containing groups of leucocytes or areas of unorganized fibrin. In some cases, at least, the organization of a fibrinous exudate with subsequent hyaline change of the new connective tissue plays an important, if not the chief, part in the production of the condition.

Peritonitis Carcinomatosa.—Scirrhous carcinoma of the stomach or gall bladder may give rise to secondaries scattered diffusely throughout the peritoneum. The membrane at the same time presents the appearance of a chronic hyaloperitonitis, the entire serosa, intestinal and parietal, as well as the hepatic and splenic capsules, being greatly thickened, dense, and hyaline. Such a condition may very easily be mistaken for a simple chronic peritonitis, inasmuch as appearances suggesting malignancy may not be visible to the naked eye. The diagnosis in some cases can be made only on microscopical examination, since the primary growth may consist only of a dense thickening of the pyloric end of the stomach or of the gall-bladder wall and may not be recognized from the gross appearances. Microscopically the hyaline connective tissue of the thickened peritoneum is seen to contain small nests and cords of epithelial cells, corresponding to those of the carcinomatous infiltration at the primary seat. It is well to bear in mind the fact that the mesenteric and retroperitoneal lymph glands may contain large nests of cancer cells, so that the diagnosis of scirrhous carcinoma may be more easily arrived at by the examination of these glands. The peritoneal condition may therefore be regarded as of the nature of a diffuse carcinomatosis with secondary inflammatory changes. More or less fibrinous exudate may be present over the surface of the thickened membrane, and some free fluid may be present in the cavity.

Experimental Peritonitis.—A number of important experimental studies of peritonitis have been carried out by different observers, particularly with reference to the etiological factors of peritonitis. The part played by various bacteria and by such predisposing factors as chemical irritation, cold, etc., has been studied with the gain of much important knowledge. Other writers have recently studied the character of the cells found in the peritoneal exudate. Beattie has made experimental investigations along this line. After the injection of bacteria into the peritoneal cavity various cells appear in the exudate. Polymorphonuclear leucocytes appear in great numbers on the peritoneal surface, and are found abundantly in from six to fifty-four hours after the injection. In fatal cases they increase up to the time of death of the animal, but in non-fatal cases they diminish in from forty-eight to sixty hours. They act as the chief bacterial phagocytes. Mononuclear phagocytes are also found at all stages, but are most abundant from thirty-six hours onward. They are derived from the endothelium of the serous membrane, of blood-vessels, lymph vessels, lymph spaces, etc. They possess amœboid motion, and are especially phagocytic to other cells, but may also take up bacteria. Great numbers of these cells are always found on the omentum, and Beattie regards them as the most important cells of the peritoneal exudate. The presence of large numbers of these cells, if they give evidences of active function, is a favorable sign. Since the omentum furnishes large numbers of the mononuclear cells in peritonitis this organ must be regarded as an important agent in protecting the body from infection by way of the peritoneum. Both the polymorphonuclear and mononuclear phagocytes are destroyed in the peritoneal sac, the former being largely ingested by the latter. In the case of peritonitis associated with secondary carcinoma of the peritoneum tumor cells may be found in the exudate in addition to the polymorphonuclear and mononuclear phagocytes. As a rule the cancer cells cannot be distinguished from the latter; but if numerous cell-division figures are present, especially atypical forms, it is very likely that such cells come from a new growth.

SYMPTOMS.—*Acute General Peritonitis.*—Peritonitis in the great majority of cases being a secondary disease the symptoms are modified to a greater or less extent by the original trouble. The onset in particular is modified.

Perforative peritonitis may occur suddenly in a person apparently in perfect health. Not infrequently the first intimation of the existence of a gastric or intestinal ulcer is the peritonitis following a perforation. In the case of perforative appendicitis the onset may be equally sudden. On the other hand, the symptoms of perforative peritonitis may be obscured in the case of intestinal tuberculosis, typhoid fever, intestinal obstruction, etc., by the severe local or general symptoms. A circumscribed peritonitis may also become gradually changed into a general condition, the change in symptoms not being so pronounced as to be noted. For example, a localized purulent perityphlitis or a purulent puerperal pelveo-peritonitis may become generalized. A pneumococcic peritonitis occurring in association with pneumonia or meningitis may have its onset obscured by the general symptoms.

In spite of these exceptions nearly every case of acute general peritonitis runs a clinical course so typical and characteristic that the recognition of the condition becomes a matter attended by little or no difficulty.

Prodromal symptoms may or may not occur. In the former case they consist of chills, prolonged and repeated chilly sensations, fever, loss of appetite, nausea, vomiting, thirst, diarrhœa or constipation, flatulence, etc.

Pain is the earliest definite symptom, and few cases of acute peritonitis exist without it. In patients who are extremely weak or whose minds are clouded, no complaint of pain may be made, and the condition may in this way escape notice. In nearly every case, however, the pain becomes the most marked and important symptom. It may be local, often referred to the region of the umbilicus, but later usually extends over the entire abdomen. The localization of the pain at the onset of the disease may have some diagnostic value in indicating the possible source of the inflammation, as, for example, in the case of gastric ulcer or a perforating appendicitis. The pain is usually excruciating in character, and may be constant, or it may occur with short remissions followed by exacerbations. Colic-like paroxysms sometimes occur. The abdomen is extremely sensitive, so that even gentle palpation, or even the weight of the bed clothes can hardly be borne. The patient assumes a position which relieves the tension of the abdominal muscles, lying on the back with thighs drawn up and shoulders elevated. Such a position may be maintained for days and weeks as long as the condition lasts. The pain is increased by deep inspirations, voluntary movements, and probably also by intestinal peristalsis. The patient fears particularly such movements as vomiting, coughing, sneezing, defecation and urination, etc. The character of the pain is sometimes described as burning, boring, tearing, lancinating, etc., without much light being thrown upon the conditions causing the especial character. The passage of gas through the coils probably plays an important part in producing the painful attacks. Though in the majority of cases the pain is most severe below the umbilicus, in cases of perforation of the stomach the pain may be referred to the shoulders, back, or chest. In the earlier stages of peritonitis following appendicitis the pain may sometimes be referred to the testicle or the penis. Mackenzie believes that the pain which is caused by pressure over the abdomen is entirely due to muscular and cutaneous hyperæsthesia, the peritoneum itself being devoid of sensory nerves. The board-like hardness of the abdominal muscles in peritonitis he holds to be the result of a violent stimulation passing from the affected organs of the peritoneal cavity to the spinal cord, where the irritation spreads, affecting not only the centres of the sensory nerves, but also those of the muscular nerves. When the patient is at perfect rest the pain may be slight or may even entirely disappear.

The *respiration* is very superficial, rapid, and wholly costal in type. The speech usually becomes an almost imperceptible whisper, occasionally hoarse and high-pitched, resembling the so-called vox cholerica. When the attack is fully established the patient presents a very characteristic appearance, the expression is anxious, the face pinched and the eyes are sunken, the Hippocratic facies being seen in this affection more often than in any other disease except cholera. The severity of the pain is usually expressed by the patient's face; in severe cases the eyes are glassy and staring. Consciousness remains preserved usually until the last; rarely there is delirium, coma, or convulsion at the end.

The abdomen quickly becomes distended, the distention becoming gradually more and more marked, and sometimes reaches such an extent that it seems that the abdominal wall must give way. The skin over the abdomen is smooth, shining, thinned, the superficial veins appearing as blue lines. Fresh lineæ albicantiæ may be seen over the surface. The abdominal muscles are stretched and often of a board-like hardness. The distention is due to the intestinal tympanites, which is sometimes so great that complete paralysis of the intestinal musculature results. The distended coils of intestine can sometimes be traced through the abdominal wall. The more lax the abdominal wall before the beginning of the peritonitis the greater will be the distention; hence the distention is most marked in the puerperal cases. When the abdominal muscles are well developed and the abdominal wall is tense, the convexity may not be great. In some cases the wall may be as hard as a board and flat or even somewhat concave. In the latter case the diagnosis may be very difficult. In the later stages the abdominal distention is increased by the fluid exudate.

Vomiting is an almost constant symptom in peritonitis. It usually begins early in the disease and causes great pain. At first the vomitus consists of food remains, later it consists chiefly of a yellowish bile-stained fluid, and finally becomes greenish. Occasionally the vomitus is brownish-black and possesses a slight fæcal odor. The attacks may be spontaneous or follow the taking of food. In the former case the vomitus consists usually of greenish mucus. Eructations of gas usually accompany the vomiting. The frequency and intensity of the vomiting vary. In some cases nothing can be retained upon the stomach, and the patient's strength is very quickly lost. The cause of the vomiting is not clear; it is probably partly reflex and partly due to pressure upon the stomach. In those cases in which the vomitus has a fæcal character the autopsy usually discloses no intestinal obstruction. It is therefore probable that the condition is due to the paralysis of the intestinal musculature and to the pressure upon the intestine. Toward the close of the attack the vomiting may be replaced by painful *hiccoughs*, which are a source of great torture to the patient. It is probable that this is due to the involvement of the peritoneal surface of the diaphragm. In those cases in which the vomiting is kept up to the end some of the vomitus usually enters the respiratory tract and may give rise to an aspiration pneumonia or gangrene of the lung.

Peritonitis not infrequently begins with *diarrhœa*, which in some cases is associated with tenesmus, or assumes a dysenteric character. The paralysis of the intestinal musculature soon leads to *constipation*, so that this condition becomes an almost constant feature of the disease.

The *tongue* is usually coated, grayish-white or brown; in cases of obstinate vomiting it may be clean and red or fissured. A very disagreeable fœtor is usually present, sometimes almost fæcal in character.

After the chill the body temperature usually rises, reaching 104°–105° F. or higher, but later usually falls. The type of the *fever* is very varied; it may be continuous, intermittent, or remittent. The skin may be cool, while the rectal temperature is high. In the case of collapse the temperature may fall even to subnormal, and the body may be covered with an abundant cold perspiration. Just before death the temperature may rise again and reach a very high point.

The *pulse* is usually very frequent, the increase in rate being out of proportion to the fever, 120–140 per minute not being uncommon. The pulse is at the same time small and soft, and in very severe cases may become imperceptible.

The number of *respirations* is increased, 30–40 per minute. The increased rate is due partly to the fever, partly to the high position of the diaphragm, and partly to the pain attending abdominal breathing. As mentioned above, the type is costal and the breathing superficial. The cessation of movement of the diaphragm is regarded as a bad sign, some writers considering the prognosis hopeful as long as an inspiratory excursion of the diaphragm can be felt, this being taken as a sign that the peritonitis is not wholly diffuse.

The *subjective* symptoms are chiefly pain, uncontrollable thirst, shortness of breath, and anxiety.

Percussion gives a tympanitic tone over the distended intestine. Dulness over the dependent portions is usually not made out until after considerable exudate has collected. When the tympanites is very marked a large amount of effusion may be present without its being detected on percussion. A change of level of the dulness with change of position does not always take place; the adhesions between the coils preventing the movement of the exudate. Moreover, there is usually too much pain to permit of a careful examination. The liver dulness is diminished, the upper border being pushed upward to the fifth or fourth rib. The splenic dulness cannot usually be made out. The heart is pushed upward, the apex beat dislocated upward and to the left. The movements of the heart in the intercostal spaces are more prominent than normal.

Auscultation of the abdomen does not throw much light upon the condition. Gurgling and splashing sounds may be heard in the intestines. Occasionally friction sounds may be heard, but these are not so common as in pleuritis or pericarditis. In pneumoperitonitis splashing sounds may be produced by shaking the patient. The heart sounds may have a metallic resonance in the case of extreme tympanites. The pulmonary second sound is usually accentuated.

The *urine* is usually diminished in amount, dark, strongly acid, of high specific gravity, and sometimes contains a small amount of albumin. The amount of indican present may be much greater than usual.

Certain writers claim that there is a *local increase of temperature* in the abdominal wall, and that this fact constitutes an important diagnostic factor. The normal temperature of the surface of the abdomen is about 35.5° C.

In the case of *pneumoperitoneum* due to perforation or to formation of gas within the cavity the hepatic dulness is obliterated. The liver dulness may, however, disappear when there is no gas in the cavity; but if the patient is placed upon his left side a clear percussion tone will be heard at the seventh or eighth rib in the right axillary line in the case of pneumoperitoneum. In other cases dulness will be found at this region. The disappearance of the liver dulness anteriorly when pneumoperitoneum does not exist is due to the tilting backward of the organ and the presence between it and the abdominal wall of a loop of distended intestine.

The *course* of an acute general peritonitis is usually very rapid. The most severe cases may terminate fatally within thirty-six to forty-eight hours, while the average case usually lasts five or six days. Since the etiological factors vary so greatly no absolute statements can be made regarding the clinical course. The peritonitis occurring as the result of gastric or intestinal perforation is usually quickly fatal, but much is to be hoped from the surgical treatment of these cases. Puerperal septic peritonitis is likewise usually fatal. Pneumococcic peritonitis is also likely to terminate more or less quickly in the death of the patient. The peritonitis which occurs in connection with arthritis, as well as in all other cases in which the exudate is serous or sero-fibrinous, is much more likely to end in recovery.

In the fatal cases *death* may occur suddenly as if from shock; or in the case of extreme tympanites the high position of the diaphragm may cause death from suffocation. In some cases the final picture is that of a general sepsis or pyæmia. In the great majority of cases the pulse becomes more rapid, the vomiting persists, the bodily powers are quickly exhausted, and the patient dies with symptoms of collapse. In such cases the temperature usually becomes subnormal as the end approaches.

In other cases of less frequent occurrence the disease may drag itself out over weeks and months, assuming the characteristics of a subacute or chronic process. Various complications may occur during such a prolonged course. Rupture of the exudate into the gastro-intestinal tract or through the abdominal wall, etc., is most likely to occur in such cases. In the event of such perforation into the stomach, pus will be found in the vomitus; when into the intestine the pus will appear in the stools; when into the urinary tract the urine will show a sediment of pus; when into the respiratory tract the sputum will be abundant and purulent. In the event of a rupture through the abdominal wall redness, swelling, and œdema will first appear at the affected spot, the skin becomes thinned, fluctuation occurs, and pus finally seeps through small fissures, or an opening of large size may be formed, through which the pus may be forced in streams during coughing, etc. The navel is the most common seat of perforation. In some cases the pus burrows beneath the skin for some distance before it finally breaks through. In other cases some of the exudate may be absorbed or encapsulation may take place. Exacerbations are frequent and death may take place finally from general marasmus. General dropsy, bedsores, albuminuria, etc., characterize the course of such cases.

In the mild cases of general peritonitis following labor, abortion, or menstruation recovery may occur. Even in those cases in which the disease runs a rapid and favorable course disturbances of the digestive tract usually develop, and the patient may die later from intestinal obstruction caused by the contraction of adhesions. A favorable prognosis should not be too hastily given in such cases. Nevertheless, complete recovery may result after a year or longer, even in very severe cases.

Acute Circumscribed Peritonitis.—The local symptoms of this form are similar to those of the general process, but are more limited. The vomiting is not so severe or so persistent as in the general inflammation. Though the general weakness is marked the symptoms of collapse do not occur to the same extent as in general peritonitis. An irregular fever is usually present, running a course suggesting that of a pyæmic affection. The condition is usually very chronic. Many patients die from general debility. Spontaneous evacuation of the encapsulated exudate may take place through perforation into the gastro-intestinal tract, pleura and lungs, abdominal wall, etc. Should the perforation take place into the remaining portion of the peritoneal cavity the peritonitis may become diffuse. According to the location of the inflammation (perisplenitis, perihepatitis, perityphlitis, perimetritis, peripancreatitis, perigastritis, epiploitis, mesenteritis, etc.) various symptoms may arise through the disturbance of function of the affected organ. Pain is usually felt in the affected region. The physical signs are local tumor, dulness, fluctuation, peritoneal friction, etc.

Of the various forms of acute circumscribed peritonitis the condition known as *subphrenic abscess* deserves especial attention. It is due to an encapsulated collection of purulent exudate between the upper surface of the liver, stomach, or spleen, and the diaphragm. Owing to the paralysis of the diaphragm the tumor may rise high into the thorax and may be mistaken for a pleural effusion, especially since a secondary pleuritis is usually present. Hepatic abscess, splenic infarction, splenic abscess, rupture of echinococcus cysts, and gall stones are the more common causes of the condition, but it is not a rare complication of perforating appendicitis.

Perforation Peritonitis.—The peritonitis due to perforation may be local or general. It may run a very

cute course, but when circumscribed is more likely to
e chronic. In the case of the sudden perforation, as,
or example, of the stomach, intestine, cystic tumor, etc.,
ie patient may feel a sharp tearing sensation, as if
omething had given way within the body. The sever-
st symptoms of collapse may immediately result. The
odomen may be contracted, hard as a board, and even
aphoid. The slightest touch causes extreme pain.
eath may take place within a few hours. In other
ses the entrance into the peritoneal cavity of stomach
ntents, fæces, bile, etc., excites a general peritonitis
ith symptoms as described above. In the case of per-
ration of the gastro-intestinal tract gas may also enter
e cavity, and the picture of a pneumoperitonitis be
esented. The liver and splenic areas of dulness are ob-
erated unless these organs have become attached to the
terior abdominal wall by means of adhesions. Suc-
ssion sounds may be produced, and the respiratory
unds may acquire an amphoric quality.

Puerperal Peritonitis.—This dreaded complication usu-
y appears at from the third to the fifth day after labor.
ety from the condition is usually assumed if the
man reaches the end of the second week without its
urrence. The pain is usually much less intense than
the other forms of general peritonitis, and the tym-
ites more marked. Chills occur more frequently than
other forms and diarrhœa is almost always present,
discharges often becoming bloody and of the charac-
of a dysentery. The vomiting is especially obstinate.
lochial discharges often become offensive. The
toneal exudate is usually more abundant and more
ulent in character than in other forms, and not infre-
ntly becomes putrid. The mortality is great, death
ng place with symptoms of general sepsis usually
een the fifth and twelfth days.

fantile Peritonitis.—*Fœtal* peritonitis occurs between
seventh and ninth months of intra-uterine life.
hilis is the chief etiological factor. Infection of the
ilicus may lead to a *peritonitis neonatorum.* The
ren of mothers suffering from puerperal sepsis are
ially likely to become infected. In addition to the
symptoms of distention, pain, etc., there is usually
ture of general sepsis or pyæmia. The condition is
st always fatal. A peritonitis may also develop in
ts and young children (*peritonitis infantium*) as the
t of syphilis, or of infection with pyogenic organ-
the pneumococcus, gonococcus, etc. In the great
rity of cases peritonitis in young children is the re-
f appendicitis. In peritonitis which occurs in young
the possibility of a gonococcic infection should
s be borne in mind and the genital passages ex-
d for the existence of such disease. Non-gonococ-
ulvo-vaginitis rarely spreads to the peritoneum.
nococcic peritonitis is more common in girl than
y infants. The infection is probably through the
l tract. The onset is usually very sudden, with
inal pain, fever, and vomiting. The course of the
on is very similar to that of pneumonia, the active
oms subsiding in from seven to ten days, but the
en remains distended, and later the presence of an
te becomes manifest. The prognosis in the cases of
l infection is not good, but when the inflammation
ized in the pelvis it is more favorable.

nic Peritonitis.—In the majority of cases chronic
peritonitis is the sequela of an acute inflamma-
lthough such an occurrence is relatively rare.
y no sharp line can be drawn between the two;
nptoms of an intense acute process gradually abate
e replaced by those of a chronic type. In some
ne chronic inflammation develops as the sequela of
er of acute attacks; in others the onset is slow
idious. The pain, abdominal tenderness, and dis-
are never so marked as in the acute cases. The
on is usually moderate and often asymmetrical,
coils of intestine being especially prominent.
nes the abdomen is flat or even scaphoid, the walls
l and board-like. On palpation the thickening
mentum and mesentery, as well as the fibrous adhesions between the coils, may be made out as tumor-like masses or as uneven prominences. When an effusion is present palpation may be negative. A friction rub may occasionally be felt. In some cases the abdomen may be so tense that nothing can be felt through it. Cases of chronic peritonitis, not due to tuberculosis or complicated with other conditions, do not usually show much exudation. The course is very protracted. Recovery may follow the absorption and organization of the exudate, or its escape by perforation from the cavity. Death usually results from general marasmus. The healing of the inflammation may be followed later by stenosis and intestinal obstruction, which may result fatally. Occlusions of the common duct by the contraction of adhesions may cause a chronic obstructive jaundice.

A peculiar form of chronic serous peritonitis occurs in children, appearing under the form of a chronic ascites. It occurs most frequently between the ages of two and ten, and in girls at the age of puberty. The abdomen is distended by the exudate, which is usually quite abundant, serous in character, and freely movable. The affected children are anæmic, more or less weak, but do not lose much in weight and do not suffer pain. The lower extremities may become œdematous. The exudate may apparently entirely disappear and then return. The course may last many months and may terminate in complete recovery. The exact nature of the affection is unknown. Trauma, inflammation of the gastro-intestinal tract, lymph glands, and genital tract, etc., have been adduced as etiological factors. It is possible that the condition represents an infection of the peritoneum with tubercle bacilli of low virulence. In the fatal cases death results from an increasing marasmus.

TUBERCULOSIS OF THE PERITONEUM.—Tuberculous disease of the peritoneum is of especial interest because of its peculiar clinical course and the fact that the condition may undergo spontaneous healing after laparotomy. A distinction is drawn by some writers between pure tuberculosis of the peritoneum and a tuberculous peritonitis; but such a distinction, while based upon pathological grounds, has but little practical value, the first condition rarely presenting clinical signs.

Simple tuberculosis of the peritoneum without accompanying inflammation or exudation is usually secondary to an acute miliary or chronic pulmonary tuberculosis. It may be secondary also to tuberculosis of the bronchial or subperitoneal lymph glands, genito-urinary tuberculosis, tuberculosis of the pleura, adrenal bodies, etc. In the great majority of cases the infection of the peritoneum proceeds from tuberculous ulcers of the intestine or caseating mesenteric glands. In rare cases it may be primary. Small grayish tubercles are found scattered over the peritoneum. On microscopical examination they consist of epithelioid cells and numerous giant cells containing tubercle bacilli. Caseating centres may be seen in the larger ones; but inflammatory changes in the neighboring peritoneum are usually wanting. The tubercles are almost always more numerous in the omentum. When very small the tubercles may not be recognized at operation or autopsy; the larger ones are recognized by their grayish color and yellowish centres. Though often very numerous the tubercles are usually circumscribed. There are no symptoms, the condition usually being discovered at autopsy, or in the event of a laparotomy.

Tuberculous peritonitis—tuberculosis with inflammation and exudation—exists in a great variety of forms which have been variously classified by different authors. The most common forms are: *acute miliary tuberculosis* with sero-fibrinous or sero-hemorrhagic exudation; *chronic tuberculous ascites* with small tubercles which show little caseation; *chronic fibro-caseous tuberculous peritonitis* with purulent or fibrino-purulent exudate; *chronic hyperplastic tuberculous peritonitis; chronic fibroid tuberculosis* with little or no exudation, the serous surfaces being fastened together by adhesions.

The appearances at autopsy or operation may vary greatly. In the majority of cases two types predominate: the *adhesive* form and that with *free fluid exudate.* The former is the more common. The coils and the abdominal organs are matted together and to the parietal peritoneum by numerous firm adhesions, in which there are found numerous tubercles or caseous masses. The spaces between the adhesions are filled with a purulent, fibrino-purulent, or hemorrhagic exudate, or, if perforation into the bowel has occurred, with exudate containing fæcal material. Such perforation is not uncommon and fæcal fistulæ may be formed. The adhesions between the liver and spleen and the diaphragm are usually very firm. The omentum is thickened and rolled up, and its boundaries are lost in the general adhesions. In many cases it is almost impossible to orient the abdominal organs, everything being so densely bound together by adhesions, all free surfaces being covered with a thick yellowish or grayish layer of fibrino-purulent exudate. In the second type the peritoneal surface is covered or strewn with numerous tubercles which are more or less confluent. Caseation is usually advanced to a greater or less extent. In the later stages the entire peritoneum becomes covered with a layer of tuberculous granulation tissue containing caseous centres. Adhesions are not numerous and the peritoneal cavity contains a large amount of serous or sero-fibrinous exudate.

In the chronic fibroid form the peritoneum is thickened and hyaline; adhesions are numerous, but there is little or no fluid exudate. The surface of the thickened peritoneum is usually covered with a fibrinous layer. Circumscribed tubercles may be entirely absent, likewise caseation. The spleen and liver may be covered with a thick hyaline layer, the appearances in general resembling those of hyaloserositis, as mentioned above, or the condition may be mistaken for scirrhous carcinoma. On microscopical examination tubercles are found embedded in the masses of fibroid tissue. These usually contain but few bacilli. In the chronic fibro-caseous form large caseating masses may be found in the adhesions or in the peritoneal surface. The chronic hyperplastic form is characterized by the formation of tumor-like masses of tuberculous granulation tissue. The mesentery may become enormously thickened, and the condition may be mistaken for a new growth. A hyperplastic tuberculosis of the intestinal wall is usually found in association with such cases. Such tumor-like masses are encountered most frequently in the right iliac region. Tuberculous tumor-like masses may also be found in the omentum.

Tuberculous peritonitis occurs at all ages, but is most common in middle adult life. The majority of cases appear to occur in females, although many statistics show a majority of males affected. Children are not infrequently affected. According to Osler the condition, in America, is more frequently found in negroes than in the white race. In the female, tuberculous peritonitis is more frequently associated with tuberculosis of the tubes; in children the infection usually comes from the intestines. The condition not infrequently occurs as a terminal infection in hepatic cirrhosis.

The symptoms of tuberculous peritonitis vary greatly. The condition may be entirely latent, and discovered only by accident. In other cases the symptoms may be so severe as to suggest intestinal obstruction. In many intances the onset is like that of an acute general peritonitis. Other cases still resemble typhoid fever and may be mistaken for this disease. The clinical picture varies to such an extent that no very general description can be given. Ascites is usually present, though the amount of exudate may be small. In the acute cases the abdomen may be distended by tympanites, and meteorism is also of frequent occurrence in the late stages of the adhesive form. Fever is always present, though sometimes light. It may be remittent, intermittent, or continuous, and may reach 103°-104° F. A subnormal temperature is not uncommon in the chronic cases, the temperature for days in some cases running 95°-97° F. The patient may appear well nourished or may be emaciated and cachectic. Gastro-intestinal disturbances are the rule, and the bowels are either constipated or loose. The skin sometimes shows pigmentation, and the condition may be mistaken for Addison's disease. The two conditions may, however, exist together. In those cases in which the tuberculous peritonitis is secondary to chronic tuberculosis elsewhere the symptoms of the former may be overshadowed by those of the primary affection. An important local sign in tuberculous peritonitis is the presence of tumor-like masses in the abdomen. These may be due to omental thickening, encapsulated exudation, thickening of the intestinal coils, enlargement of the mesenteric glands, caseating masses, nodules of tuberculous granulation tissue, etc. A friction rub may often be felt over the tumors. The omentum is frequently rolled up and thickened, forming a rope-like tumor lying transversely across the abdomen above the level of the umbilicus. In connection with the symptoms this local sign is of great importance in the diagnosis of tuberculous peritonitis.

The disease pursues a varied course. Spontaneous healing may occur. In the severe acute cases death may take place suddenly as in acute general peritonitis not due to tuberculosis. In the chronic cases the patient may gradually become marasmic and die from general weakness. The course of the affection is subject to various complications which may bring about a fatal termination. Obstruction of the intestine from the contraction of adhesions, perforation of the exudate into neighboring organs, fatal hemorrhage, etc., are the most common of these. Death may take place from the primary tuberculosis, or a general miliary tuberculosis may terminate the case. The prognosis in tuberculous peritonitis has, however, been greatly modified by the results of laparotomy.

Diagnosis.—The diagnosis of acute general peritonitis is usually very easy in those cases in which there is a characteristic picture of abdominal tenderness and distention, vomiting, and collapse. The starting-point of the inflammation is often very evident in cases in which a primary condition, such as typhoid fever, gastric ulcer, puerperal infection, etc., has already been recognized. Careful inquiry and search for such a cause should always be made. A history of previous attacks suggesting appendicitis, of pelvic disease, gastric ulcer, etc., aids greatly in establishing the starting-point. Such a cause cannot always be easily determined. Since many cases are first seen only after the tenderness and distention are marked, the physical examination cannot always be as thoroughly carried out as is desirable. In such cases the pelvic organs should be examined thoroughly. In some cases the diagnosis becomes very difficult, since similar symptoms may be produced by other conditions. Acute enterocolitis, acute intestinal obstruction, intestinal ulcers, acute hemorrhagic pancreatitis, ruptured tubal gestation, embolism of the superior mesenteric artery, rupture of an abdominal aneurism, etc., may present the picture of peritonitis so that it may be impossible to say whether the latter condition has been set up or not. A diagnosis of peritonitis may be given under these conditions when no evidences of it can be found at autopsy. The mistake may be easily made in those cases of typhoid fever in which the tympanites, abdominal pain, and constitutional symptoms are very marked. The presence of parasites in the intestinal tract may also give rise to symptoms suggesting peritonitis. In those cases in which the local symptoms are not marked, while the general collapse is severe, the diagnosis may be entirely missed.

The diagnosis of circumscribed peritonitis is almost wholly dependent upon the recognition of the condition from which the inflammation proceeds. This cannot always be accomplished, and it is often necessary to study the case for some time before a diagnosis can be made. The condition is most often mistaken for a tumor. On the other hand, the distended bladder and pregnant uterus have been mistaken for peritonitis. In doubtful cases aspiration of local tumors should always be carried out.

The diagnosis of chronic peritonitis is sometimes very lifficult in so far as a differentiation between simple hronic peritonitis and tuberculous peritonitis is con- erned. It may be borne in mind, however, that the ormer condition is very rare. In those cases in which it s a sequela of an acute process the previous history of he case usually clears up the matter, but in those cases n which the disease develops gradually and insidiously he determination of the nature of the process may be ery difficult. The patient's family and individual his- ory must be considered, a careful examination of the horax and genitals must be made, the abdomen aspi- ated, and the exudate examined. A hemorrhagic ex- date favors tuberculosis. Carcinoma may be diagnosed y the finding in the exudate of small bits of tumor tis- ue or cells containing atypical division figures. The xudate should also be stained for tubercle bacilli, and nimal inoculations may be made. The tuberculin test ay also be given. The occurrence of pulmonary, pleu- tic, or genito-urinary tuberculosis makes it almost cer- in that the peritoneal condition is likewise tuberculous. n children the symptoms of the condition known as *tabes senterica* are chiefly due to the tuberculous peritonitis resent. Tuberculous peritonitis is often a terminal ent in hepatic cirrhosis.

Blood Examination.—The red cells are usually dimin- hed in all forms of peritonitis, to a slight or moderate gree in acute forms, but in the chronic cases the anæ- ia may be marked. During the acute febrile stage the ucocytes are usually slightly increased. In purulent ritonitis the leucocytosis may be more marked, but metimes is not present or the leucocytes may even be minished. In perforative peritonitis the beginning of e inflammation may be marked by a leucocytosis. In phoid fever perforation may be marked by an increase the polymorphonuclear leucocytes, or the percentage these may rise without an increase in the total num- r, or the leucocytes may not be affected. Likewise in pendicitis a very high leucocytosis is suggestive of a ginning peritonitis. In tuberculous peritonitis with- t obstruction and secondary infection with pyogenic ganisms, the leucocyte count is usually low. As a le leucocytosis in this disease is a sign of a compli- ion.

Hysterical Peritonitis.—Cases have been reported of sterical conditions in which all the symptoms of peri- itis were simulated: sudden onset, abdominal disten- n, pain and tenderness, vomiting, symptoms of col- se, etc. Fever may also be present. The cases ally give a history of recurrent attacks without ap- ent cause. Other hysterical symptoms may be want- so that a mistaken diagnosis may easily be made.

REATMENT.—The treatment of acute peritonitis has n much discussed in recent years, particularly from operative side, and as a result of improved surgical thods the prognosis in this so frequently fatal con- ion has been greatly improved. There is much con- ting opinion as to the exact details of the treatment, l various writers even disagree as to more essential nts. A survey of the literature, however, seems to icate that the principle of early surgical interference gaining ground. As a prophylactic measure in the e of an impending perforation operation has in some rters met with notable success. With improvement he surgical technique much may be hoped from the y surgical treatment of cases of acute general peri- itis, and it is not improbable that this disease, at sent so dreaded, may be divested of much of its im- tance.

he older treatment may be summed up as follows: , opium or morphine, local applications, hot or cold, l application of leeches, milk diet, ice, small quan- s of soda water, etc. In cases of distention the stines were sometimes tapped with a fine trocar. intestinal tube was also used to remove gas from the e bowel. Much discussion has also been waged over use of salines in this condition, some authorities ad- ating them as an aid to the removal of the exudate, others condemning such use on the ground of danger in the case of intestinal lesions.

While in general the above outline of treatment is still carried out in many cases, important modifications have been made, and the surgical treatment is coming more and more to the foreground. Mikulicz, Krönlein, Oberst, Wagner, Trever, Péan, and Körte were among the first to advise laparotomy for general peritonitis. Many other writers have recently followed in their lead. The operative treatment in general consists of opening the abdomen, removing the exudate as completely as possible, the so-called "toilet of the peritoneum," and after-drainage. The earlier in the disease, especially in the case of perforative peritonitis, the more likely is the operation to be successful. Authorities differ in their views as to the value of washing out the peritoneal cavity. Some recommend very highly the use of large quantities of sterile physiological salt solution, all parts of the abdomen being thoroughly flushed. This seems a rational proceeding, and from the published reports a number of cases have undoubtedly been saved by it. Appropriate general treatment is of course given, intravenous saline injections being freely used during the after-treatment. In those cases in which adhesions have already formed the washing out of the exudate is more difficult and less perfect. This fact is therefore the chief reason for operating as early in the disease as possible. Mikulicz advises several incisions for the purpose of draining and flushing localized collections of exudate.

On the other hand, Krogius does not advise the flushing out of the cavity, apparently for the reason that he does not think it accomplishes the desired purpose. He recommends the dry absorption of the exudate, all parts of the peritoneal surface being thoroughly mopped with sterile gauze compresses and particular attention being paid to the pelvis and the subphrenic space. In order to render all parts of the peritoneum accessible he makes two incisions through the abdominal wall, one along the lateral border of the right rectus, the other along the lateral border of the left. If the exudate in the pelvis cannot be removed through these openings, he advises a counter-opening in the posterior wall of the fornix vaginæ in women, and a parasacral opening in males. After cleansing the peritoneum as perfectly as possible, large Mikulicz iodoform tampons are placed in the pelvis and in the upper and lower portions of the abdominal cavity. These become offensive in a few days and are renewed, the outer dressings being frequently changed. In addition he uses intravenous saline injections, intestinal irrigation, and morphine when necessary. The occurrence of secondary collections of exudate, particularly subphrenic abscess, should be watched for and when found they should be opened and cleansed. Although these principles are applied chiefly to perforative peritonitis occurring in appendicitis they may be utilized in the treatment of all forms of acute general peritonitis.

The surgical treatment is particularly applicable to local circumscribed peritonitis. The encapsulated exudate should be evacuated by incision or puncture, and the cavity washed and treated as a chronic abscess cavity. The details concerning drainage, packing, after-treatment, etc., must be left to the judgment of the operator.

In the case of subphrenic abscess an incision may be made at the edge of the ribs, or the transpleural route may be followed by resecting several ribs. In the chronic forms with multiple adhesions relatively little can be expected from operative procedures.

In the case of tuberculous peritonitis laparotomy is at present the only method of treatment offering hope of improvement or cure, and is universally advised for this condition. The fact that a tuberculous peritonitis may spontaneously heal after laparotomy was accidentally discovered by Spencer Wells in 1862. So much has been written upon this subject that the reader is referred to some one of the recent monographs relating to it. The relation between the laparotomy and the cure of the tuberculosis is wholly unknown, although numerous theories—effects of daylight, evaporation, irritatio the peritoneal surface, promotion of healthy granulation-tissue formation, increase of the peritoneal resistance, hyperleucocytosis, increased bactericidal action of the exudate, etc.—have been advanced in explanation. Surgeons differ very much in the details of technique in their operations upon such cases. Some open the abdomen and remove the exudate with dry sponges; others flush with warm physiological salt solution; others still wash out the cavity with solutions of salicylic acid, etc. There is also a difference of method in regard to the removal of the organs (tubes, lymph glands, etc.) primarily affected. In general it may be stated that laparotomy is indicated in all cases of tuberculous peritonitis in which the general condition of the patient permits, or in which there is no evidence of cerebral, pulmonary, or extensive glandular or bone tuberculosis. The medicinal treatment of tuberculous peritonitis is advised in some cases, the administration of iodoform as well as its use by inunction having been reported as resulting in cures. Cases of cure have also been reported as following the use of tuberculin.

Very recently a number of writers have been advising conservatism in the treatment of acute general peritonitis by operation. Those who advocate a medicinal method modify the older methods by giving no food by the mouth, employing rectal feeding, allowing no ice, checking thirst by wet gauze to lips and by rectal injections, giving no cathartics, administering small doses of morphine, and applying continued cold to the abdomen. This treatment is based upon the theory that the peritoneal exudate itself may weaken the virulence of or destroy the germs gaining entrance to the cavity. Alcohol has been strongly advised in the treatment of puerperal peritonitis, large and frequent doses being given.

The injection of purgatives directly into the intestinal canal has been advised and as strongly condemned.

Some surgeons advise against operation in sthenic cases of perforative peritonitis without symptoms of sepsis, on the ground that spontaneous resolution may occur. There is, however, a great danger that such cases may under the influence of morphine be allowed to drift along until too late.

Hot vaginal douches have been strongly recommended in cases of pelvic peritonitis. If the external genitals are protected injections of water at 40° C. may be given without discomfort. The pelvis should be elevated, and about 4–5 litres of water used for the irrigation daily. Tampons of glycerin or potassium iodide with glycerin are applied after the irrigation. Stratz in particular claims good results from the application of this method in pelvic peritonitis associated with pyosalpinx.

The statistics of the results of the treatment of acute general peritonitis by operation are very encouraging. Krogius in his monograph published in 1901 has made an elaborate study of the results of operation in general peritonitis following appendicitis. The percentage of cures ranged from 28.5 to 46.

Surgical interference in the case of impending perforation of gastric or intestinal ulcers, appendicitis, rupture of sac in ectopic gestation, salpingitis, necrotic ovarian cystomata or subserous uterine fibromata, hemorrhagic pancreatitis, etc., has proved of the very greatest value as a prophylactic measure. With improved methods of diagnosis much may be hoped for by the further development of such prophylactic operations.

The literature of peritonitis is enormous. Collections of bibliography will be found in the article by Döderlein in Veit's "Handbuch der Gynäkologie," and in the one by Eichhorst in Eulenburg's "Real-Encyclopädie." An exhaustive review of the literature of peritonitis from the year 1885 to 1900 is given by von Bruns (*Cent. f. allg. path. Anat.*, 1901.) *Aldred Scott Warthin.*

PHYSICIAN, RELATION OF, TO THE LAW.—In this we have a subject of much interest and importance, yet one that is too little known among the profession at large. Experience, while a valuable teacher, is, where the law is concerned, a very expensive one; so it is the duty of every practitioner to familiarize himself with the laws having a medical aspect, remembering that local, not national, statutes prevail.

In several States medical jurisprudence is one of the subjects of examination as conducted by the State Board of Examination and Registration, and is given equal importance with the other branches, as it should be, for there is no more pitiful sight than to see a medical witness, bright in other subjects, held up to ridicule by attorneys because of ignorance of the legal requirements of the particular case in question.

Judges throughout the Union try to sustain the same rulings along general lines, but it is impossible to lay down fixed rules for all sections of the country in an article of this nature, as the wording of the statutes differs in almost every State; hence they are capable of various interpretations.

License to Practise.—In many of the States good laws have been enacted requiring that the applicant for license present a diploma from a recognized school, showing the necessary training to qualify him for the work which he desires to undertake. Some States, in addition to the presentation of a diploma, require an examination before a State or local board, and will admit no one to the practice of medicine and surgery until a certificate of qualification is issued to the applicant by the Board of Examiners.

After the applicant has received the necessary State documents it is his duty to present the same and his diploma for record to the clerk of the county in which he desires to locate. In case of removal from one county to another the papers must be again recorded in the office of the county clerk. The law must be complied with in every particular, else non-recognition will result if he should be called into court.

If one is located near a county or State line, cases can be attended in the adjoining county or State without a record in the same, provided the practitioner be legally recognized in the county and State in which he is located.

In case of change of location to another State all the local laws must be investigated and fully complied with, the physician going before examining boards if necessary.

As a measure cannot be made retroactive, those who have qualified under former acts are entitled to all the rights and benefits of the law existing at the time of their qualification. In many of our Western and Southern States are to be found legal practitioners who received their medical training as members of a hospital corps during the civil war, or as apprentices of physicians who established themselves in a legal way under the very lax laws that formerly covered the practice of medicine in these localities. Many of these men, being keen observers, and having had the advantages of short post-graduate courses, do much good.

Different Schools.—Under the law the members of the different schools have equal rights. Each is allowed to practise the method in which he has been trained, and he can recover by law such fees as he can prove that he has earned, even if men of other schools testify that the treatment given was not all that it should have been. Decisions have been rendered in several States granting freedom of practice to osteopaths when it was fully demonstrated that their principles in the handling of infectious and malignant cases were faulty.

Malpractice.—In order to recover in a malpractice suit it is necessary to prove that the attending physician or surgeon did not use or display ordinary skill in handling the case in question. This ruling gives a wide latitude in arriving at what constitutes "ordinary skill." A city practitioner, with vast opportunities in hospital work, is expected to have greater skill than the man in country practice whose opportunities are necessarily limited.

A recent ruling of the Superior Court of Cincinnati set aside a judgment rendered in favor of the plaintiff by a lower court, on the ground that expert testimony had not been introduced to show that the attending physician had failed to use or display ordinary skill and care in the handling of this particular case. This ruling is most wise and will no doubt be the cause of much less annoy- ınce, to say nothing of loss of time and money, to the rofession generally, as unscrupulous attorneys have in ecent years been filing suits against physicians who vere fortunate enough to possess funds or property, in he hope of blackmailing by a so-called compromise, ealizing that the majority of men would rather pay hem a fee than stand suit under the older rulings.

Like others under the law the physician is liable for amages if he is careless and neglectful in his work. Vhen he is employed to treat a case the contract is im- lied, and the person or persons employing the medical an are to understand, when the case is accepted, that rdinary skill is to be shown.

Suggestive Therapeutics.—This subject, which has at- acted considerable attention in recent years, is one that as its legal complications if carried too far.

A Cincinnati physician was recently indicted on the arge of obtaining money under false pretense as a re- ılt of erroneous ideas as to the scope of this line of eatment. A woman who had been under the care of a ımber of physicians for some time, going first to one ıd then to another, decided to make another change and lled in the man in question. After going into her his- ry, perhaps realizing that his predecessors had done all at was possible in a strictly medical way, he decided at hers was a good case for suggestion, and to this end formed her that she had a tumor which it would be cessary for him to remove. The patient consented and ıs removed to a hospital for the operation. As an en- metritis existed, the womb was curetted, and, after effects of the anæsthetic had disappeared, the pa- nt was informed that the operation was successful. e attending physician reported that the recovery s rapid, and that the patient had fully recovered from pre-existing symptoms. After a time the patient ted to be shown the tumor which had been removed. veral excuses were offered, but the patient was per- tent; so, to continue the suggestion, the woman was wn a piece of beef so arranged as to resemble a tumor. some manner it was suggested that a section be made l studied by a pathologist to ascertain the nature of growth. This suggestion was acted upon and the ımor" was sent to a well-known man for examination l report, with the result that criminal proceedings e begun against the too ardent advocate of sugges- ı.

n all cases in which suggestion is likely to benefit, nbers of the family should be consulted and their con- ; and co-operation obtained. If actual deception is sidered necessary a consultation should be arranged, he facts bearing on the case reduced to writing, and document signed by the attending physician, the con- ant, and some responsible member of the family, and ı carefully filed for reference.

ı all cases of suggestion the charges made for service lered must be in accordance with the work actually ormed, else fraud will be claimed and established.

ıses Having a Legal Aspect.—All cases of this nature ıld be considered in every possible detail, and full s should immediately be made and recorded in a per- ent form for future references. A judge is always e opinion that a doctor should notice everything, if he fails in his examination on the witness stand, public is ready to censure him and the opposing at- ys make light of his ability in their arguments.

a physician is called to see an individual dying as esult of accident, assault, or attempt at self-destruc- who is capable of making an ante-mortem state- , he should insist that the latter be reduced to writ- signed and witnessed. Before his statement is taken atient must be informed that death is certain to fol- as dying declarations are of great legal importance, this point must always be made. The simple nent of an injured person who may be of the opin- ıat recovery will follow, is of very little value.

en viewing a dead body the physician should note its position, not alone as regards the relation of its members and the surface on which it lies, but also as regards its relation to all surrounding objects. Very careful inspection must be made of the surface of the body and of all wounds, scars, marks, livid spots, and other abnormal conditions; they should be measured and the results should be recorded, together with exact descriptions and a statement of their anatomical relations.

As rigor mortis is of value in determining the state of health at the time of death, this feature must not be overlooked. A note must also be made in regard to the following: Whether the surface of the body is livid or pallid, what expression the face bears; whether the body is warm or cold, as revealed by the temperature of the mouth or the axilla; the exact time at which the body was seen; the condition and nature of the clothing; the contents of the pockets; whether there was any jewelry; at what time—giving hour and place—the person was last seen alive, and whether he or she was alone; if vomited matter is present, collect some of it for chemical analysis; note the presence or absence of weapons, drugs, bottles, or other possible clews.

If a post-mortem examination is necessary to establish the cause of death, every vital organ should be thoroughly examined. The stomach and intestines should be examined for inflammation, and if such areas are found the exact seat and possible nature must be determined. The contents should be collected for examination. The amount, odor, color, and other characteristics are to be noted. If death by poisoning is suspected, the stomach, liver, intestines, and kidneys should be removed for a chemical examination. All vessels used for the collection of vomit, or of other fluids and organs removed, must be known to be perfectly clean and not to have been where contamination with arsenic, strychnine, or mercury could have been possible. Note whether the rectum is empty or filled with fæces; the latter condition indicating that purging could not have taken place. Carefully examine the lips, mouth, pharynx, larynx, œsophagus, and trachea for evidences of the corrosive action of poison.

Note whether there is an abnormal amount of fluid in the pleural cavity, pericardium, cranium, or spinal canal. Thoroughly investigate the action of the valves of the heart.

In cases in which death has resulted from the slow action of poison it is important to investigate the changes which may have taken place in the kidneys and liver. In all cases of death from an unknown cause the best way of arriving at a definite conclusion as to whether death was due to natural or to violent means is by the slow process of exclusion. Full notes along this line will make the position of the medical witness secure, as he is then prepared to meet the attack of attorneys when by cross-examination they try to make the point that death could have resulted from other causes.

When the medical man is called upon to make an examination of a body that has been buried, it is necessary that the body be identified by some one who can positively state that the body in question is the one ordered examined, else the point will be made and sustained that it is possible that the wrong body was exhumed.

Criminal Assault.—This is a subject often brought to the attention of the medical witness, especially in the case of children below the age of ten. Noma pudendi, when discovered by those in charge, is often thought to be the result of an assault, and the afflicted child, not understanding the true nature of the questions asked, will make admissions that result in serious charges being preferred against an innocent person. The other extreme is to be considered at all times in connection with assault, as in rare cases only the most careful examination will reveal physical signs; for wounds and abrasions of the hymen and vagina heal rapidly.

Casper[1] reports a case in which, on examination eleven days after the assault, no signs of the outrage could be observed.

The leucorrhœa common in childhood is often the cause of rape charges. Children of a scrofulous habit may present points of ulceration about the vagina and vulva, accompanied by a purulent vaginal discharge, so that in any case the presence or absence of gonococci must first be determined and deductions made accordingly.

A child, as a rule, makes little or no resistance at the time of assault; so the bruises and other marks of violence usually observed in older females are absent and the case resolves itself into ascertaining the cause of abnormal conditions about the genital tract.

As false charges are sometimes preferred by older females, it should always be the rule to look upon all cases from this point of view when beginning the examination. If marks of violence are shown, ascertain the time of the alleged assault, and observe whether the wounds or bruises are older than the time indicated; also obtain all the facts as to the manner of the assault, and note whether the marks of violence presented could have resulted in the manner described.

When an examination of the genital tract is made it must be remembered that the hymen is at times destroyed as the result of a purulent discharge, and also that, in some women, it is destroyed at the beginning of the menstrual period. On the other hand, the presence of an intact hymen is not a positive sign that penetration has not taken place. The important thing, in such cases, is to determine whether or not the vaginal canal has been dilated.

In the event of assault on a married woman, or on one who is not a virgin, evidences of injury to the genital tract may or may not exist. If the assailant is alone in his deed, marks of violence are always to be found about the person of the victim, often including the vulva and vagina, for the resistance offered causes undue force to be used in penetrating. If the assailant, however, has assistance, either manual or in the form of drugs, no signs of assault may be present. Where drugs have been administered, their character must be discovered, if possible, and their physiological action fully investigated, in order that it may be shown that hallucinations have not led to the making of the charge. The hallucinations produced by the administration of anæsthetics for slight operations have resulted in dentists being accused of rape.

A case of extreme interest is that of a young woman who was violated while asleep. She had returned from a long walk with her accepted admirer, had drunk a glass of ale, then had fallen asleep in his presence, and the assault followed. Owing to the fact that she was an unusually heavy sleeper, the pain produced by laceration of the hymen and distention of the parts had not been sufficient to awaken her. An examination by a competent medical man revealed the usual physical signs of recent defloration, and the assailant admitted his guilt when charged with the crime.

The medical witness is usually concerned in cases of young children and the feeble-minded; the testimony of the victim commonly establishing the charge in adult cases.

Criminal Abortion.—While we, as a rule, divide the expulsion of the fœtus before the normal termination of intra-uterine life into abortion, miscarriage, and premature delivery, the law regards all under the one head.

It is the duty of the medical witness to distinguish between natural and violent abortion, and, if the cause be violence, to ascertain whether it was criminal or accidental in character. Criminal abortion may be produced by mechanical means or by the use of drugs acting upon the uterus. When mechanical means are used, marks of the violence can usually be demonstrated on the mother and on the expelled fœtus, unless the work has been done by one thoroughly familiar with the anatomy of the parts, and who exercises great care when he introduces the instrument for the purpose of rupturing the membranes.

The use of medicinal substances, by profoundly shocking the system and in this indirect way affecting the uterus, at times produces abortion. When seen the patient is usually giddy, nauseated, and purging. Drugs, even ergot, can be expected to cause an evacuation of the uterus only after the third month of gestation, the muscle fibres not being well enough developed prior to this time to respond; in fact, it is rare that the effect can be obtained until the fifth month of pregnancy is reached.

The diagnosis, shortly after evacuation, is rendered easy by a careful examination, which should always be made, as cases of feigned abortion are on record and similar ones will no doubt occur again.

When a physician is called to see a case in which the evacuation of the uterus seems imperative, he should request a consultation, and a full and complete history should be obtained and reduced to writing, if abortion is decided upon.

Infanticide.—By this term we mean the murder of a new-born child. In perhaps no class of cases is the medical expert so handicapped as in this. Many children die shortly after birth, yet live long enough for well-known evidences of this fact to exist, and the question to be determined is whether death was due to natural causes or to violence. Marks of injury may show on almost any part of the body of the infant and be due to forces acting at the time of delivery. The first question that presents itself when one views a dead infant, is what is its age; and in this connection it must be remembered that the younger in uterine age the infant is, the greater the danger of death at birth or shortly after.

The child should be weighed and measured and all details in regard to its degree of development should be recorded, especial care being taken to note the size of the head as compared with that of the trunk, the degree of ossification, the color and thickness of the skin, and whether the surface of the brain is smooth or already presents convolutions. If the child is fully developed it must be determined whether it lived to breathe and whether it was born alive; for, it must be remembered, a child may breathe and yet be born dead. Experiments have taught us that in a still-born child the forcing of air into its lungs in an attempt at resuscitation will produce the same condition as that of a child who was born alive but breathed only feebly. It is only after all these details have been most carefully observed that the physician may feel warranted in forming a trustworthy opinion. In atelectasis the child may be born alive and exist for some hours, yet the lungs will sink in water, even when divided into small portions.

In those infants who have lived long enough to feed, the presence of food or other foreign substances in the stomach proves that the child was alive at birth, and if death is the result of poisoning, the appearance of the gastric mucous membrane or the usual chemical analysis will reveal the cause of death. It must be remembered, however, that it is possible for an infant, still-born, to have amniotic fluid or other contents of the parturient canal in its stomach as the result of an effort to breathe, the material having been drawn into the mouth during such effort and then swallowed before death ensued.

Death from suffocation is very common in the new-born; it may be due to some malformation, to weakness, to the blocking of the air passages with mucus or other substances, or to the effects of too heavy covering. Where destruction is intended and a damp cloth or other impermeable material is placed over the mouth and nostrils, death will result; and if the act has been done without the employment of undue pressure, the medical witness will be at a loss to state whether the child was born alive or dead, his opinion being possibly in favor of the latter view.

Birth Records.—The medical attendant should write down at the time the exact date and hour of birth, the sex of the child, the state of its development and all characteristic marks, and he should place this record on file for reference. In many legal battles such a record has been of value in determining the right of inheritance and has aided in dealing justice where fraud has been attempted. Male children have been substituted for female, living children for those born dead, and a perfect

hild for a monster who would not be recognized as a
gal heir.

Insanity.—Under this heading we shall not consider
ose cases in which the insanity is marked by hallucina-
ons and impairment of all functions, but preferably
ose in which only a careful study will enable the medi-
l witness to determine whether the patient in question
or is not sane, and those who are feigning insanity.

No definite law can be laid down as to what constitutes
sanity; all symptoms must therefore be carefully
udied and deductions drawn from them for the benefit
the court.

Persons displaying unnecessary hatred to those about
em are often presented for examination as to their san-
, as this characteristic is offered in evidence in case of
iminal proceedings against them; but unless it can be
own that there is some impairment of the faculties of
ention, comparison, and volition, the individual can-
t be adjudged insane. The faculties should be ex-
ined when the patient is not conscious of the object
the visit made. Ordinary subjects of general conver-
ion should be used in this examination and mental
te made of any and all irregularities, which can be re-
ced to writing as soon as possible after the examination
oncluded. During the examining visit some subject
uld be introduced which requires that the patient
ll write a letter of his own composition which, in
uine cases of insanity, will give evidence of the con-
ion that can readily be demonstrated. Patients of this
ture should be repeatedly examined, as many of them
sent lucid intervals.

erhaps the most common condition in which the aver-
practitioner is called to testify is that of setting aside
ill, the charge usually being made that at the time of
cution, or possibly of alteration, the patient was not
ound mind. When attending a case in what appears
e the last illness, the physician should note carefully
patient's mental condition from visit to visit, and he
uld preserve a record of these observations, in order
he may be able, if called as a witness, to state
ther the supposed irregularities were due to a weak-
l mental condition or to an eccentric disposition.

the case of criminals for whom is entered a plea of
nity, a careful study of their history and the facts
conditions of the crime committed will usually clear
he medical aspect and enable the physician, when on
witness stand, to be sure of his ground.

sane person will be found to have a motive for the
e, be it plunder or revenge; he is often assisted in
crime and will at first usually deny guilt, except in
s in which the motive for the crime is notoriety, as
e assassinations of Presidents Garfield and McKinley.
nsane person will have no motive, or only a fancied
for the commission of the crime, and, instead of one
m, as would be the case if the murderer were a sane
on, he will often kill several, perhaps those most near
dear, and will make no attempt to cover up his tracks
ny the act.

fe Insurance.—Where life insurance is concerned, the
cal witness is of importance in determining—for the
faction of the heirs of the deceased, of the company
ing the liability, and of the court, if legal action has
started—as to whether death was the result of
ral or of violent means. In the case of a natural
it is important to learn how long the individual
suffered from the disease that caused death, and
her or not there were predisposing chronic patho-
al conditions existing prior to the issuance of the
y covering the case involved. On the other hand,
th resulted from violence, it is necessary to ascer-
vhether the cause was criminal, accidental, or sui-

ident insurance having now become an extensive
ess the attention of the profession is frequently
to cases that require the utmost care in arriving at
nite opinion. Diabetic ulcerations are stated to be
esult of trauma (a wound received in a barroom
or an injury caused by a fall)[1] or a syphilitic ulceration is claimed to be the result of a burn, and so on through the entire list of diseased conditions that produce lesions which can be charged to an accident.

Shrewd criminals often conceive unique plans for defrauding insurance companies, and the medical witness must always be on the alert for such surprises. Postmortem examinations should always be insisted upon when a case is not absolutely clear.

Partnership.—Agreements are often entered into by members of the medical profession for mutual benefit and a firm name selected. The basis for settlement is decided upon and division made accordingly, but no legal responsibility is assumed by one for the other, and each member of the firm is alone responsible for errors made in his professional work. Should the firm enter jointly into outside investments, they then become liable under the law to the same extent as do the regular commercial unions.

Fees.—The question of fees has ever been a hard one for the medical profession. The courts have ruled that no one is so good a judge as to the number of visits necessary to be made in a given case as the medical attendant, and he can so render an account. In several States fee bills have been enacted regulating the maximum amount to be charged for certain classes of work. As nearly every case—especially those wherein the amount of the bill rendered is claimed to be exorbitant—possesses certain complications, it is not hard for expert opinion to prove to the court or jury that the fee charged is not excessive. By far the most common question that arises in this connection is not the amount, but who shall pay the fee. A prominent Cincinnati surgeon recently sued a corporation for services rendered an employee and lost his case, the court ruling that the defence had proven that the individual who employed the doctor, although he was connected with their concern, had no authority to make contracts, and was simply acting as a messenger for the injured person, and that the patient must be looked to for liquidation of the account.

When answering calls where it is probable that the individual requiring the service will be unable to pay for the same, the physician should ask some one in authority to become responsible. It is not sufficient for a person in authority simply to ask the medical man to assume charge of a case, he must also agree to settle for the service rendered; otherwise liability can be denied and this defence will be sustained by the court. In nearly all sections of the United States this ruling has prevailed where medical men have been called to attend an injured passenger or employee by local agents, conductors, and other minor officials of railway companies. The same ruling applies in cases in which parents have requested attendance upon their children of legal age; the patient being considered liable while the parent is looked upon as a simple messenger without liability. In the case of the wife, legally absent from home, the husband is held to be responsible for medical attention rendered; if, on the other hand, she is not legally absent, she alone is considered responsible.

Consent of Patient.—In cases of injury, or in those in which it has been determined that an operation is necessary, it should always be the rule to obtain the consent of the patient to do whatever is necessary after administration of the anæsthetic. In case the patient is not in a condition to understand, or if the patient is a minor, then the consent of a responsible member of the family or guardian should be obtained. Occasionally one meets with cases in which the individual claims to prefer death to the loss of a limb, and if he still persists in this view after all the facts are set forth, his wish must be respected. It is needless to say that every avenue for a malpractice attack must be carefully guarded either by securing in advance reliable disinterested witnesses or by resigning the case if another practitioner can be found who is willing to assume charge.

Consent procured by misrepresentation has no standing in law.

Mr. Benjamin Vaughan Abbott, in his excellent article on this subject in the first edition of the HANDBOOK, cites a case of much interest, as follows: "A lady became suspicious that a housemaid in her employ had become pregnant, taxed her with it, and gave her notice of dismissal. She denied it. The lady sent for her family physician and ordered the girl to go to her room and submit to an examination. The girl protested, but went to the room followed by the physician. She objected to each of the doctor's requirements, as to removing her clothing, etc. However, she obeyed, remonstrating all the while, and the usual examination was made, resulting in the doctor being satisfied that the charge was groundless. But the mistress dismissed her, notwithstanding. A lawsuit was brought on behalf of the girl against the physician, for damages for assault. The case was several times discussed in court, with the final result in the physician's favor. The courts considered that although the girl remonstrated, yet as she went to her room, undressed, and lay down to be examined, all without being forced, the examination did not take place in a legal sense without her consent. It was a case of reluctant obedience to arbitrary, wrongful command, as distinguished from a forcible compulsion which she was powerless to resist."

Emergencies.—While there is no definite law covering the rights of the profession at large in emergencies, the courts would no doubt sustain any action necessary for the well-being and safety of the public. Health officers are given a wide latitude in all matters of public hygiene and safety and should always be appealed to if possible.

Relation of Physician and Patient.—The relation of patient and physician is acknowledged by law to be most intimate. Any abuse of this confidence on the part of the physician would in all probability render him liable in a suit for damages. Abbott[2] reports a case from the Michigan courts in which a physician was assessed damages for allowing a non-medical man to be present and render slight assistance at an obstetrical case, notwithstanding the fact that the physician showed that circumstances required his being accompanied by the man in question, and that there was no other protection from the prevailing storm than the room in which the woman was confined.

In damage suits the ruling has been made that the attending physician may testify as to what the patient said regarding the manner in which the accident occurred, it being held that the law in its strict sense refers to those things necessary for the physician to know regarding family history, habits, etc., for the proper treatment of the case, and not to voluntary admissions made during the visit. This ruling would not hold in criminal cases if the patient should admit that a wound had been received while doing a dishonest act. Here the ruling has been made that this is imparted in confidence and must not be revealed under any circumstances. On the other hand, the law will not protect a third party, guilty of crime, but will allow the testimony of the attending physician to assist in conviction. To illustrate, we will consider the case of a young woman dying as a result of criminal abortion. Here all the facts were given the attending physician as a dying statement. This was admissible as evidence to aid in the conviction of those responsible for her condition. In the case of State *vs.* Pierson, the latter was charged with having caused the death of one Withey by the administration of arsenic. In this case the physician who attended Withey in his last illness was allowed to testify as to what he saw and heard. This was sustained by the Court of Appeals under the ruling that the law was to protect the patient and physician in legitimate communications, not to shield criminals.

Wills.—It is not often that the physician is concerned in the drawing of such documents, and it should be avoided if possible, especially if complicated details are to be arranged or the doctor is to be a beneficiary. In cases of emergency it may be necessary for the attending physician to draw up the will, in which case any simple, but clear, form will be sufficient. Have the instrument signed and witnessed by three or more competent individuals and deliver the document into safe hands.

Mark A. Brown.

PHYSICIANS: RELATIVE NUMBER AS COMPARED WITH EXISTING POPULATIONS.

PHYSICIANS: RELATIVE NUMBER AS COMPARED WITH EXISTING POPULATIONS.—The relative number of physicians in any country or population depends upon many circumstances and conditions, such as the laws governing the practice of medicine, the progress of medical education, the prevalence of empiricism, and many other social conditions.

In some countries the number may be ascertained from the figures of the census; in others, as in Germany, from careful enumerations of the medical profession made by the Government.

In the United States at the present time certain medical directories, issued at frequent intervals, contain this information, with an approximate degree of accuracy.

The following tables present the numbers of physicians per 10,000 of the population in each of the United States in the two years 1898 and 1902:

RATIO OF PHYSICIANS TO THE POPULATION IN THE UNITED STATES IN 1898 AND IN 1902 IN GROUPS.

States and Territories.	Ratio of physicians to the population, 1898.		States and Territories.	Ratio of physicians to the population, 1902.	
California	23.8	More than 20.	California	26.1	More than 20.
Iowa	23.7		Colorado	23.4	
Indiana	21.4		Vermont	21.5	
Vermont	20.8		Indian Territory	20.7	
Ohio	20.3		Oklahoma	20.6	
Illinois	19.3	13.3 to 20.	Missouri	20.3	
Arizona	19.1		Ohio	20.3	
Missouri	19.0		Arkansas	19.7	13.3 to 20.
Colorado	18.7		Indiana	19.7	
Tennessee	18.6		Maine	18.8	
Massachusetts	18.5		Iowa	18.4	
New Hampshire	18.1		Kansas	18.4	
Maryland	17.9		Illinois	18.3	
New York	17.7		Tennessee	18.2	
Texas	17.5		Maryland	18.1	
Arkansas	17.2		New Hampshire	17.8	
Maine	16.8		Michigan	17.6	
Kentucky	16.5		Massachusetts	17.2	
Nevada	16.3		Texas	17.2	
Michigan	16.0		New York	16.9	
UNITED STATES	15.4		Kentucky	16.3	
Connecticut	15.2		Nevada	16.3	
Rhode Island	15.2		UNITED STATES	15.9	
Oregon	14.9		Pennsylvania	15.4	
West Virginia	14.9		Oregon	15.3	
Pennsylvania	14.9		Rhode Island	15.2	
Oklahoma	14.4		West Virginia	15.1	
Florida	14.4		Connecticut	15.0	
Delaware	14.2		Washington	14.9	
Montana	14.0		Delaware	14.7	
Idaho	13.8		Arizona	14.5	
Kansas	13.6		Nebraska	14.3	
Virginia	12.3	10 to 13.3.	Georgia	14.2	
Georgia	12.3		Idaho	13.4	
New Jersey	12.1		Montana	13.2	10 to 13.3.
Alabama	11.9		Florida	13.1	
Washington	11.3		Wyoming	13.0	
Wisconsin	11.3		Alabama	12.2	
Louisiana	11.0		New Jersey	12.1	
Mississippi	10.9		South Dakota	12.1	
Utah	10.2		Virginia	12.0	
Minnesota	9.6	8 to 10.	Wisconsin	11.5	
Wyoming	9.4		Utah	10.7	
Nebraska	9.2		Alaska	10.7	
South Carolina	8.7		Minnesota	10.6	
North Carolina	8.5		Louisiana	10.6	
North Dakota	7.8	Less than 8.	Mississippi	10.1	
South Dakota	7.7		North Dakota	9.3	8 to 10.
New Mexico	7.2		New Mexico	8.5	
			North Carolina	8.2	
			South Carolina	8.1	

Allowance has been made in the foregoing tables for increase of population.

Examination of the foregoing table shows that the ratio of physicians in the United States has increased from 15.4 per 10,000 inhabitants in 1898 to 15.9 in 1902.

The ratio had increased in each of 29 States and Territories, and had decreased in 19. Alaska and the Indian Territory are included in the second list, but not in the first.

The States in which either the increase or decrease appears to have been excessive are Iowa and Arizona, with decrease of 22 and 24 per cent. respectively, and Kansas, Wyoming, Oklahoma, Nebraska, and South Dakota with increase of 35, 38, 48, 55, and 57 per cent. respectively.

The map or chart shown herewith was constructed for the year 1898 and presents the ratio of physicians to the population by means of different shadings, black indicating the highest ratio.

The information obtained from these figures must be deemed to be only approximately accurate, since the two essential factors, namely, the directory list of physicians and the census enumeration of the population, with the necessary estimates for intercensal years, cannot be regarded as strictly correct in a rapidly growing country like the United States, subject to the constant change which attends the migration of population, not only from foreign countries to the United States, but also from one State to another.

In general, however, the figures for the larger States, and for the New England, Middle, and Southern States, embraced in all the groups except the first, may be considered to be fairly trustworthy.

The figures for the Philippine Islands, Hawaii, and Porto Rico are not given in the table, since they can hardly be regarded as valuable for purposes of comparison. The ratio in Hawaii is stated to be 5 per 10,000, and in Porto Rico and the Philippines less than 1 per 10,000.

The relative number of physicians in other countries is generally less than it is in the United States. Prinzing* published the following figures in 1901 for the principal European countries:

Number of physicians and surgeons to each 10,000 inhabitants: In Germany, 5.1; in Austria, 4.1; in Hungary, 2.8; in Italy, 6.3; in Switzerland, 6.1; in France, 3.9; in Spain, 7.1; in Belgium, 5.2; in England, 6.1; in Scotland, 7.7; in Ireland, 5.6; in Denmark, 6.4; in Norway, 5.3; in Sweden, 2.7; in Russia (European), 2.7.

The number of homœopathic physicians in the principal states of the German Empire were as follows:

In Württemberg 30 or 3.7 per cent. of the whole number of physicians.
In Russia 136 or 0.9 of one per cent. of the whole number.
In Baden 8 or 0.9 of one per cent. of the whole number.
In Saxony 15 or 0.8 of one per cent. of the whole number.
In Bavaria 16 or 0.6 of one per cent. of the whole number.

At the last enumeration of physicians in the German Empire, the whole number of homœopathic physicians in the empire was stated to be 240, or less than 1 per cent. of the whole number of practitioners, which was 27,874.

The number of physicians in Germany has increased, both absolutely and relatively, from 13,728, or 3.2 per 10,000 inhabitants in 1876, to 27,874, or 5.1 per 10,000, in 1900.†

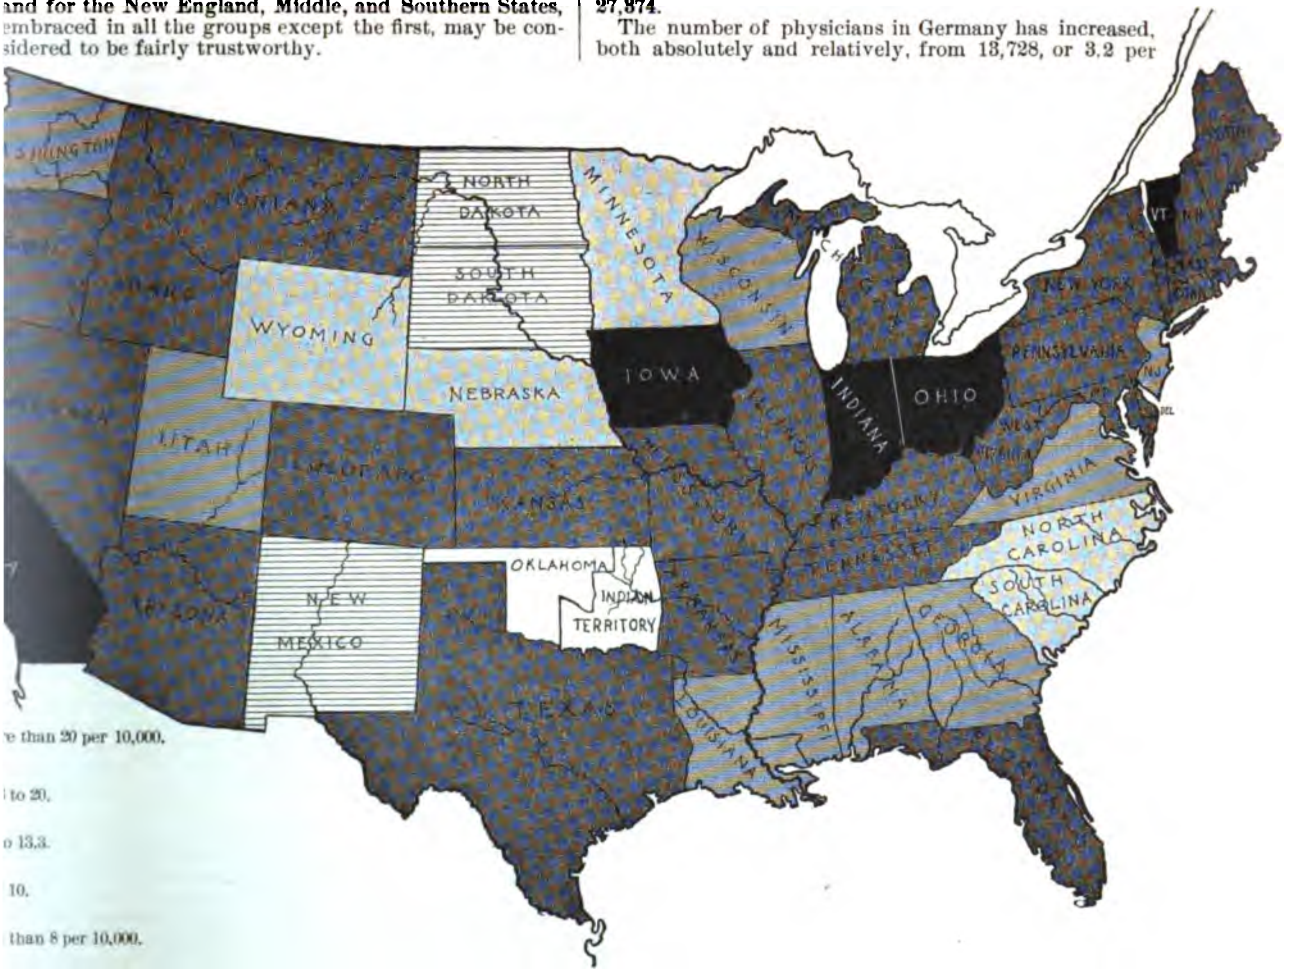

FIG. 5162.—Ratio of Physicians to the Population in the United States, per 10,000 Inhabitants in 1898.

---

* Zeitschr. f. Socialwissensch., 1901, Bd. 4, Hft. 7.
† Rheinischer Kurier, 1901, No. 415.

In the whole of Prussia there were registered in 1900 16,100 physicians, 956 dentists, and 3,118 apothecaries.[*]

Prinzing also states that quackery has gained so strong a foothold in Germany as to demand energetic measures for its suppression. Weavers, barbers, shoemakers, and persons of other ordinary occupations are often found practising as physicians.

The relative number of quacks in 1898 in the principal German states were as follows· In Saxony, 16.4 per 10,000; in Württemberg, 5.5; in Prussia, 5.8; in Bavaria, 4.5; in Baden, 2.9; in Hesse, 2.9; in Alsace-Lorraine, 1.3.

The veterinary surgeons in Germany at the last enumeration were 3,813 in number, and when compared with the class of patients whose ills they are called upon to relieve, were found to be in the proportion of 1 to every 1,240 horses and every 5,677 head of cattle.

The proportion of physicians in the cities is, as might be expected, much greater than that of the rural districts. For example in Germany in 1876, in the cities and towns having more than 5,000 inhabitants in each, the ratio of physicians was 7.5 to each 10,000 inhabitants, and in the rural districts only 1.8 per 10,000. These figures had increased respectively to 8.4 and 2.4 in 1898.[†]

The ratios of physicians in the great cities of Europe and the United States were as follows during the years named: London (1895), 12.8 per 10,000 population; Paris (1896), 9.7; Berlin (1900) 14.1; Vienna (1896), 13.0; Brussels (1897), 14.7; Budapest (1896), 16.4; Madrid (1899), 24.4; New York (1901), 17.1; Chicago (1901), 20.5; Philadelphia (1901), 21.8; St. Louis, 26.3; Boston, 26.8; Baltimore, 23; Cleveland, 21.9; Buffalo, 19.6; San Francisco, 31.5. *Samuel W. Abbott.*

PITYRIASIS ROSEA.—Pityriasis rosea is a disease of the skin characterized by the development of symmetrically distributed patches, roundish or circinate in outline, slightly scaly and of a faint red color. It is one of the rarer dermatoses. The disease has been described under several names. Pityriasis rosea, the name given it by Gibert, is the one nearly universally used now. It was described by Hebra under the name herpes tonsurans maculosus, and by Bazin under the title pityriasis maculata et circinata.

SYMPTOMATOLOGY.—The eruption occurs in two forms, the macular and the circinate. Probably the first lesion in both forms is a very small pinkish macule or papule which rapidly spreads to form the characteristic macule or patch of the disease. In the macular type the lesions are roundish patches, gradually fading into the healthy skin, of a pinkish color and covered with fine branny scales. These patches vary in size from one-sixteenth to three-quarters of an inch in diameter, and are of a reddish to fawn color. Frequently the periphery of the lesions will show the erythematous color while the centre will be fading.

The circinate type of the disease differs from the macular in that the tendency of the patches to spread peripherally is more marked. In this form the border spreads while the centre fades. The typical lesion of this form, therefore, is a more or less circular patch with a pinkish border and a fawn-colored scaly centre. Adjacent patches of this sort may coalesce and thus form peculiar gyrate figures. These patches do not usually become larger than an inch in diameter. By the time they reach that size the reddish border breaks up and fades out, leaving the characteristic fawn-colored stains of the disease. The lesions are apt to occur in successive crops, so that it is possible to see at one time the minute papules of the beginning of the disease, along with the patches and circinate figures of a later stage of the process. At times the eruption remains papular for the most part throughout its entire course, only a few patches or circinate figures developing.

Brocq called attention to the fact that a single primary patch, usually of large size and situated upon the abdomen, preceded by ten days or two weeks the general eruption, and this observation has been confirmed by other dermatologists.

The extent of the eruption varies very greatly. In some cases it is confined to one or two regions, but most frequently it is widely distributed. It occurs by preference on the front and sides of the abdomen, over the chest and on the buttocks, and on the sides of the neck. It may be universal, but it rarely develops on the face or below the elbows and knees. There is also considerable variation in different cases in the color of the lesions, which at times show an inflammatory red but more frequently a pinkish or fawn color. The eruption usually disappears in from two or three weeks to two or three months, but cases not infrequently last longer, even for four or six months.

The appearance of the eruption is usually preceded by a slight rise of temperature with general malaise, but these systemic manifestations are usually so slight as to pass almost unnoticed. There may be some enlargement of the lymphatic glands. This may be confined to the submaxillary and post-cervical glands. At times also the axillary and inguinal glands show slight painless enlargement. There is slight itching, particularly at night, or when the patient gets overheated, but it is not of severe character and causes little or no annoyance.

ETIOLOGY.—The etiology of the disease is unknown. Like the exanthemata and other toxic eruptions it occurs most frequently in children. It was thought by Hebra to be a mycotic affection, and this view still has its advocates. Its symmetrical distribution, the accompanying slight febrile disturbance, and the character of the eruption seem to indicate that it is closely allied to erythema multiforme.

HISTOPATHOLOGY.—Microscopically the changes found are those of a slight inflammatory process in the skin.

DIAGNOSIS.—The exceedingly trivial character of the systemic disturbances and the duration of the eruption serve to distinguish it from the exanthemata. From psoriasis and widely distributed forms of seborrhœic eczema occurring in small patches, it is distinguished by the lack of infiltration of the patches, the much lower grade of inflammation, and the character of the scales, the fine branny scales of pityriasis rosea presenting no similarity to the coarser scales of psoriasis and seborrhœic eczema. From tinea circinata it is distinguished by its much wider distribution, the rapid development of the lesions, and the absence of the ringworm fungus. It is most likely to be confused with the squamous and circinate syphilides, from which it is distinguished by more rapid development, less scaling, absence from the face and hands, and the absence of concomitant symptoms of secondary syphilis.

TREATMENT.—The disease requires very little treatment. Constitutional treatment should be symptomatic. Certain authorities think they have seen benefit from the use of salicylic-acid compounds. A mild antipruritic dusting powder, or lotion or salve is all that is necessary in the way of local treatment. *William Allen Pusey.*

PITYRIASIS RUBRA.—Pityriasis rubra is a dermatitis, usually subacute or chronic in intensity, in all but the most exceptional cases universal, and characterized by abundant dry desquamation. Other names by which the condition is known are dermatitis exfoliativa (Wilson), pityriasis rubra aigu (Devergie), erythrodermie exfoliante (Besnier). It is a rare disease.

SYMPTOMATOLOGY.—The disease may begin primarily as pityriasis rubra, or it may develop upon other inflammatory dermatoses. When occurring primarily it may begin in either of two ways. In some cases it begins as a diffuse hyperæmia, which increases until the skin becomes a bright red, and with the increase in redness there is the development of the characteristic desquamation. In other cases it begins as circumscribed red scaly patches. These spread peripherally and new patches form at the same time, until the entire surface becomes involved in the process. In the early stages of the disease the skin is of a bright, hyperæmic red color, which fades on pressure, and the induration is very slight. As the process becomes older the redness becomes of a deeper hue, and in some cases has presented a markedly venous character. There is also at times, even when arsenic has not been used, the development of marked pigmentation in the skin. The true color of the skin is more or less concealed by the abundant grayish scales which cover it. The abundance of this desquamation is one of the most salient characteristics of pityriasis rubra. The scales are dry and grayish in color; at times they are fine, but usually, except on the face, they occur as thin papery flakes. On the palms and soles the horny epidermis exfoliates in large flakes, which may at times amount to masks of the parts. The scales are easily detached and quickly reform. A quart or more of scales may be produced in twenty-four hours, so that they can be collected by the handful from the patient's bed. There is usually very slight induration of the skin, although after the disease has persisted for a long time the skin may become considerably indurated and stiffened as a result of the chronic inflammatory process. Rarely is there any free exudate. Except for perspiration the skin is dry, although a certain amount of weeping and even the formation of bullæ have been described. When we come, however, to cases of this character, accompanied by bullæ and free exudation, the border-line between this disease and pemphigus foliaceus becomes confusing.

---

[*] R. Wehmer: Medicinal-Kalender, Berlin, 1901.

[†] Vierteljahrsschrift f. öff. Gesundheitspflege, 1902, vol. xxxiii., Suppl., p. 402.

There is more or less involvement of the appendages of the skin. The growth of the hair is interfered with and much falling of the hair takes place. At times the accumulation of scales underneath the nails causes them to be raised up and thrown off. Again the nails may become thin and softened and stunted or lost entirely. In some cases the nails become thick and rough and striated. The secretion of sweat is usually much diminished, but there may be an increase on such parts as the axillæ and genito-crural fold. The tongue in most cases is bright red, undoubtedly due to the exfoliation of the epithelium, which is washed away in the saliva.

The subjective symptoms are relatively unimportant. In rare cases the itching is severe, but usually it is of trivial character or absent. The sensation is more apt to be one of tenderness, burning, and stiffness of the skin. The onset of the disease is usually accompanied by a temporary febrile disturbance, which may recur with each exacerbation of the process. Except for such slight disturbances there may be no positive illness, although there is usually an indefinite lowering of the general physical tone, which becomes more marked as the disease progresses. Later on, the patients become anæmic, cachectic, and emaciated, and thus become the ready prey to intercurrent affections. Insanity, and other mental and nervous disturbances have been noted in a number of the cases.

The acute cases are often accompanied by very violent constitutional symptoms, with all the evidences of grave septic or nutritional disturbance. The temperature may range as high as 105° or 106° F. There may be great depression, diarrhœa, rigors, and a typhoid condition, and death may occur in one or two weeks.

Etiology.—The cause of the disease is unknown. It is probable that several conditions, essentially different, present this complex of symptoms. It is rare in children and occurs most frequently after middle life. It is more frequently observed in men than in women. Crocker thinks there is a close relationship between acute rheumatism and gout and pityriasis rubra, eleven out of eighteen cases which he analyzed having shown this relationship. Jadassohn has pointed out the frequency of the association of tuberculosis in some form with pityriasis rubra. It is recognized that pityriasis rubra may supervene upon psoriasis, eczema, and other inflammatory affections. Brocq has seen a severe acute attack brought on by the vigorous application of chrysarobin, and Crocker has seen it follow vigorous inunctions with mercurial ointment and the external use of arsenic. Stelwagon has seen it develop on the extremities after the use of quinine by patients who had an idiosyncrasy as regards that drug. As an exciting cause, sudden chilling of the body has in some cases seemed to have a direct relationship to the development of the disease, and in other cases it has been excited by alcoholic debauches.

Pathology.—Microscopically the disease shows nothing to differentiate it from other simple inflammatory processes in the skin. There are the usual changes of a superficial dermatitis, and when the disease has persisted for a long time there are the connective-tissue changes characteristic of chronic inflammation of the skin. Several efforts have been made to discover central or peripheral nerve changes in connection with the disease, but without definite findings.

Diagnosis.—The involvement of the entire skin, which occurs in all but the rarest cases, the profuse dry desquamation, the slight induration, together with the rapid development, are the prominent characteristics of the disease.

If it is admitted that psoriasis or a squamous eczema could become absolutely universal and of uniform type of eruption throughout, it is possible that they might be confused with pityriasis rubra. It is hardly likely, however, that this ever occurs. A universal psoriasis could be differentiated by the gradual development, the greater induration of the skin, and the thick, silvery white, closely adherent scales of that disease, and the hemorrhagic puncta following the forcible removal of the scales. It is hardly conceivable that an eczema could show a uniform type of eruption over the entire body, such as is seen in pityriasis rubra. Additional points of distinction from eczema would be the yellowish crusts of eczema, the presence of more or less free exudate, less rapid onset, greater induration of skin, more itching, and less evidence of constitutional disturbance.

The two conditions with which pityriasis rubra is likely to be confused are pemphigus foliaceus and pityriasis rubra pilaris. In pemphigus foliaceus there is the occurrence of flaccid bullæ, which, if not seen themselves, at least leave traces of their existence in undermined borders of epidermis and in the excretion of serum and pus, which dries in crusts upon the surface and gives rise to the sickening characteristic odor of pemphigus foliaceus. Pityriasis rubra pilaris does not develop so rapidly as pityriasis rubra, is not so likely to be universal, is accompanied by much greater induration of the skin, and shows the characteristic papules, which are entirely absent in pityriasis rubra. These rough, dry, horny papules, capping the hair follicles and giving the skin the nutmeg-grater appearance, that are seen on the back of the fingers and hands in pityriasis rubra pilaris, are entirely absent in pityriasis rubra.

Treatment.—The patients are made much more comfortable by emollient local applications. The essential thing is to keep the skin thoroughly lubricated. This may be done with vaseline, rose ointment, olive oil, lanolin, or mixtures of these in the form of liniments. The internal treatment is symptomatic, and is directed toward building up the patient's general health. Arsenic and quinine have both been advised empirically without very strong evidence of their having any specific effect. The patients should be carefully protected against chilling, and they do best when they stay in bed. There is little evidence that treatment has any effect except in relieving symptoms. *William Allen Pusey.*

PITYRIASIS RUBRA PILARIS. See *Lichen Ruber Acuminatus.*

PONS AND MEDULLA, DISEASES OF THE.—It is a fortunate fact that the occurrence of vascular lesions, such as hemorrhage, embolus, and thrombosis, is rare in the neighborhood of the pons and medulla. They may of course occur in the presence of such a favoring element as cardio-vascular disease, which in turn may be due to a variety of causes, but when they are of any considerable size they are so quickly fatal that a determination of their exact location within the above structures is practically impossible. It is, moreover, not particularly easy, even though the lesion be so small as to be compatible with life, to locate it with absolute definiteness, and this in spite of the fact that the industry, both of the clinician and of the pathologist, has guided us to a remarkably clear comprehension of the physiologic values of the various nuclei, nerve fibres and tracts which lie in and traverse this anatomically complex territory.

In the case of extensive hemorrhage the victim is struck down so suddenly, and unconsciousness supervenes so rapidly that it is impossible to separate the damage to individual nuclei from the general havoc which the lesion entails. Certain features are, however, usually present which indicate in a measure the general situation of the extravasated blood. The respiration, for instance, rather quickly assumes the Cheyne-Stokes character, and this in itself should arouse a suspicion of the intimate relationship between the hemorrhage and the respiratory centre. Conjugate deviation of the eyes is also a fairly reliable indication of ponto-medullary hemorrhage, the eyes being turned toward the side opposite the lesion. The resultant paralysis is apt to be bilateral even though the hemorrhage be unilateral and differs from the flaccid type observed at the outset of an ordinary apoplexy in the tendency of the extremities to assume a degree of rigidity. This rigidity may be accompanied by a recurring shock-like tremor of a rather coarse type. The behavior of the reflexes is not sufficiently constant to be dependable, and there is nothing strikingly characteristic about the pulse and temperature.

In arterial lesions of lesser grades of severity the symptoms may be grouped in a variety of ways, dependent upon their site and extent. A lesion involving the pyramidal tract in the upper pons produces an ordinary hemiplegia, but if it be sufficiently extensive to include the facial nucleus, or even its roots, there usually results a so-called alternating hemiplegia; that is to say, a facial paralysis corresponding to the side of the lesion and a paralysis of the opposite side of the body.

A similar type is observed where the nucleus of the sixth nerve is included in the lesion. In other cases both the abducens and the facial nerves may be involved on the side of the vascular disturbance, and the resulting paralysis may be associated with hemiplegia of the opposite side of the body. Oftentimes the disturbance lies not exactly in the sixth nucleus, but near by in the conjoined centre for the sixth of the same side and the opposite rectus. This produces the conjugate deviation of the eyes away from the side of the lesion spoken of above.

The variety of clinical combinations which may occur in vascular lesions of the ponto-medullary region is relatively extensive. An examination of its anatomy reveals the fact that it contains the nuclei of the larger part of the cranial nerves, nuclei which serve also as trophic centres. It contains furthermore centres governing the respiration and the heart's action; likewise the great tracts and network of fibres which have to do with motion, sensation, and equilibration. The act of vomiting, the secretion of the saliva, and the vaso-motor activities of the body also doubtlessly depend upon centres located in this important region. Nowhere else in the central nervous system are so many important structures in such close proximity; hence it is easy to understand the eccentric grouping of symptoms arising from simultaneous destruction of nuclei and nerve tracts, both sensory and motor.

To attempt to give in detail all the clinical combinations to which acute vascular lesions of this region may give rise would be as fruitless as it is impossible, the element of fortuitousness being too strongly in the ascendant. Generally speaking the onset of trouble is marked by rather severe vertigo, which may be accompanied by vomiting of equal severity. Consciousness is seldom profoundly disturbed, hence the patient is able to observe and give an account of his troubles. These may consist of the alternating hemiplegia above mentioned, or may be further complicated by a more or less extensive loss of sensation, by ataxia of the upper or lower extremities, by difficulty in speech and in swallowing, by diplopia, or by a complete loss of control of the facial muscles which externalize the emotions.

As stated above, it is impossible to construct a semeiology which will fit every case. The point always to be emphasized is the eccentric grouping of symptoms indicating nuclear palsy combined with more or less extensive implications of the motor and sensory tracts.

The prognosis in this class of cases is fairly good as regards life. The damage to the nuclear elements is, however, practically permanent, the resultant paralysis being for the most part of the atrophic type.

Treatment is of little avail except in cases in which syphilis is the etiologic factor.

The medulla may be involved during the course of many diseases of the central nervous system, notably tabes, progressive muscular atrophy, multiple sclerosis, gliosis, and amyotrophic lateral sclerosis. It may also be the seat of tumor, abscess, or tuberculous disease. As none of these diseases can be classed as peculiar to the medulla no further consideration will be given them in this article.

The next disease of essentially medullary origin to be considered is the so-called

PROGRESSIVE BULBAR PARALYSIS.

(Labio-glosso-laryngeal [Pharyngeal] Paralysis.)

It is to be classed among the rare forms of nervous disease. Its victims are, in the large majority, found among the aged. A so-called infantile type will be spoken of later. As to its etiology nothing definite is known, hence the usual train of causative factors comes in for mention, namely, exposure to cold, traumatism, mental wear and tear; and even abuse of function of the lips, tongue and palate, although it appears that women are less commonly afflicted than men.

SYMPTOMATOLOGY.—The first thing that attracts the patient's attention is an unwonted fatigue after talking for any length of time, with a restricted ability to enunciate certain syllables. The initial disability lies, as a rule, in the articulation of the lingual consonants, *l*, *r*, *n*, and *t*. The tongue can at first still be protruded, but not to the normal extent, and there may be a difficulty in securing its proper apposition to the roof of the mouth for sounding the linguo-palatine consonants *t* and *d*. Up to this time the continuous sibilant *s* may be pronounced. With the increasing weakness of the lips whistling becomes impossible and there is an inability to utter the sounds in which the lips are chiefly concerned, such as *o*, *u*, *b*, *p*, and *m*. So imperfectly are the lips brought together and so sluggish is their separation that the labial explosives *b* and *p* degenerate into *m* and *u*. Finally weakness of the palate fails to shut off the nasal cavity, and a part of the expiratory air stream escaping through the nose gives a nasal quality to the voice, *b* and *p* sounding as *mb* and *mp*.

At this stage of the disease dysarthria is fully established. Words are run together and indistinctly articulated, with an intonation of a decidedly nasal quality. Single words may still by special effort be brought out clearly, but sustained speech of any clearness is impossible.

Either at this time or more commonly after the disease has been established a few months the patient experiences a difficulty in swallowing. Only by great effort can food be carried back through the pharynx to the œsophageal opening. Fluids are constantly regurgitated through the nose, and at times are inhaled into the larynx causing choking and paroxysms of coughing. Ultimately neither fluid nor solid food can be successfully swallowed. Chewing also becomes progressively difficult.

Finally both phonation and respiration become involved. The voice is weak and monotonous and lacks modulation. Hoarseness may develop and go on to complete aphonia. Toward the end respiration becomes labored, and not uncommonly severe attacks of strangulation occur.

Examination of the larynx shows in the beginning nothing abnormal; later, paresis of the adductors is obvious. The masticatory muscles betray their weakness by imperfect closure of the jaw and restricted lateral movements of the same.

Bulbar paralysis is of the degenerative type. Atrophy is, however, not an early symptom and almost never keeps pace with the paralysis. It is usually first observable in the tongue, which becomes lax and feels flabby and spongy; the fibrillary twitching is very striking. Ultimately the organ undergoes a marked grooving and furrowing, and its total volume is much diminished. The lip muscles are rarely affected until late in the course of the disease. They then become thin and toneless. The muscles of the jaw are only rarely markedly wasted, although a fibrillary twitching is not infrequently observed in them at an early stage.

The electrical excitability of the diseased muscles is never greatly altered. Late in the course of the disease there may be some quantitative change to faradism, but examination is never very satisfactory.

When the disease is far advanced the expression of the face is very characteristic and striking. The mouth is open, the lower lip sunken; and drooling is constant. The fixed and expressionless lower part of the face contrasts strangely with the still mobile muscles of the upper face and eyes, which alone afford mimic externalization of intellectual activity. The patient is very emotional and cries easily, but even then the mouth is but little discomposed, whereas the respiratory muscles are thrown into a sort of spasm to which is sometimes added a peculiar respiratory stridor. The shrunken, furrowed tongue lies motionless on the floor of the mouth, articulation is almost annihilated, and the feebly mumbled speech incomprehensible. The respiratory movement is hurried and the pulse may run as high as 140 per minute. Emaciation is very marked.

The above symptomatology develops on the basis of a paralysis of cranial nerves which are purely motor, and there is never implication of nerves which are sensory or sensorial. Curiously enough, however, in certain cases there is to be observed a peculiar heightening of tendon reflex irritability in the facial and masticatory muscles.

DIAGNOSIS.—Bulbar paralysis has so many features that are peculiar that its differentiation from other affections of the medulla should present no special difficulties. The gradual character of its onset and development, its practical restriction to persons of advanced age, the symmetrical implication of purely motor nerves with absence of sensory and sensorial disturbances, and the association of paralysis with atrophy are all factors which serve to crystallize out the disease from other affections of the same region. The features which further distinguish it from acute bulbar paralysis and from the pseudo-bulbar form will be considered later. Tumors of the medulla involve all structures in their neighborhood; hence, sensory nerves suffer as well as motor; furthermore tumors produce the usual train of symptoms characteristic of a general increase of intracranial pressure.

PATHOLOGICAL ANATOMY.—The essential morbid change in bulbar paralysis is a progressive decay of the motor nuclei of the facial, hypoglossal, and glosso-pharyngeo-vago-accessory, and occasionally of the trigeminal. The ganglion cells of these nuclei lose their processes, shrivel, and gradually disappear. The intranuclear reticulations and the intra- and extrabulbar roots undergo the same destruction, the change in the latter being sufficiently marked in certain cases to be obvious macroscopically. In some cases the pyramidal tracts are involved.

PROGNOSIS.—The disease is, for the most part, steadily progressive and invariably ends fatally. Its duration varies from one to three years. Remissions rarely occur, although in any case there may be protracted periods during which there appears to be no advance in the symptoms. In quickly progressing cases the disease may run its course in less than a year. Death usually ensues by reason of asphyxia, bronchitis, inhalation pneumonia, inanition, or some intercurrent disease.

TREATMENT.—Many drugs have been tried, but none is of any special value. Strychnine in gradually increasing doses, arsenic, nitrate of silver, and the iodides are among those most strongly recommended. Forced feeding should be instituted early in the attempt to keep up the nutrition, and later, when dysphagia is established, the food should be introduced artificially into the stomach in order to avoid the very imminent danger of inhalation pneumonia.

A galvanic current of two or three milliampères passed from one mastoid to the other is recommended by Oppenheim.

Vocal gymnastics may be tried in the effort to improve the speech.

The Hereditary (Familial) Type of Progressive Bulbar Paralysis.—A few cases of a peculiar hereditary form of progressive bulbar paralysis have been observed among members of the same family, usually among the offspring of consanguineous marriages. The victims are practically always true degenerates. The peculiarity of the disease in these cases is that it usually affects the upper facial territory first and its effects are most marked in this region, ophthalmoplegia, especially ptosis, being associated with the bulbar phenomena. These latter do not differ from those observed in the ordinary form.

The paralysis is in most cases of the atrophic type and is associated with partial reaction of degeneration.

In 1895 Oppenheim described an infantile form of pseudo-bulbar paralysis. It was observed by him in connection with cerebral infantile diplegia, and consisted of a bilateral paralysis or paresis of the muscles of the tongue, palate, pharynx, and larynx, which gave rise to the characteristic dysarthria, dysphagia, etc. The paralysis was associated with spastic athetotic movements of the affected muscles. Atrophy and fibrillary twitching were absent.

Oppenheim considers the pathologic basis of the disorder to be a bilateral disease or a developmental defect in the central convolutions.

THE ACUTE (APOPLECTIFORM) TYPE OF BULBAR PARALYSIS.—*Symptomatology.*—Certain cases have definite prodromes, such as pressure in the head, ringing in the ears, vertigo, sleeplessness, and spots before the eyes. The main symptoms develop suddenly. Intense vertigo or even a genuine apoplectic shock with complete loss of consciousness may usher in the attack. Vomiting may accompany the vertigo. In a few cases general convulsions of an epileptiform character have been observed.

Almost immediately after onset a labio-glosso-laryngeal paralysis is found in full development. This is manifested by characteristic dysarthria, dysphagia, etc. Although the paralysis is bilateral it rarely affects the two sides equally. In the majority of the cases the extremities are also involved in the same varying degrees. There may be paralysis of both arms with simple weakness of the legs, or there may be simple hemiplegia, the latter usually on the side opposite to that on which the bulbar nerves are most involved. The onset of all these symptoms may be less sudden, a few days or even a week being required for their full development.

Dyspnœa and even Cheyne-Stokes respiration, with marked increase of the pulse rate, may be present early and may last for a very long time.

Various sensory disturbances are not unusual, and the patient may complain of painful paræsthesiæ in some parts of the body or extremities.

The expression of the face is characteristic; more so in fact than in the early stage of the chronic type of bulbar paralysis, because the disease renders the facial muscles fixed and expressionless in a very short time.

The paralysis of lips, tongue, and soft palate is naturally not often associated with atrophy—first, because this phenomenon requires time; and, second, because it is the supranuclear part of the nerves which is usually affected. The nucleus itself may be directly affected, though rarely, and in such cases the characteristic atrophy with electrical changes may be found in the affected muscles.

The symptomatology is much more variable than in the chronic bulbar form, and naturally varies with the extent and seat of the lesion. The same eccentric grouping of bulbar nerve paralysis, with paralysis or paresis and sensory disturbance in the trunk and extremities spoken of under vascular lesions of the bulb in general, is to be expected.

Pathological Anatomy.—By far the commonest cause of the acute form of bulbar paralysis is thrombosis with softening. Both hemorrhage and embolism do occur, but with nothing like the same frequency. Poliencephalitis inferior acuta may determine the symptoms above described, and like symptoms are also ascribed to the pressure of a dilated atheromatous basilar artery.

Certain authors have observed the occurrence of an acute bulbar paralysis associated with weakness of the extremities during the course of typhoid; sometimes with a fatal outcome. In the latter cases streptococci and other organisms were found in various parts of the central nervous system without any very marked histological changes.

Prognosis.—Death may result, in very acute cases, within a short time from inhalation pneumonia or cardiorespiratory paralysis. In less severe cases the symptoms are slowly regressive and may gradually disappear, although restoration of function is seldom absolute in all the affected parts.

Treatment.—In cases suspected to be of syphilitic origin the prompt and free use of specific medication is demanded. Otherwise treatment should in the main follow the lines indicated in the therapy of cerebral vascular lesions in general. In the cases which arise in the course of an encephalitis of the ponto-medullary region antiphlogistic and derivative measures are appropriate. Very large doses of calomel may serve a useful purpose even in cases not syphilitic.

It is very important to make every effort to keep up the nutrition from the beginning. As paralysis of the muscles of deglutition may be absolute even from the outset, artificial feeding often becomes indispensable. In the later stages of surviving cases electricity may prove useful.

Labio-glosso-laryngeal Paralysis of Pseudo-bulbar and Cerebro-bulbar Origin.

In very rare cases after a patient has experienced a number of minor apoplectiform attacks a condition resembling the labio-glosso-laryngeal paralysis of bulbar origin, without any implication of the bulb itself, may result.

The pathologic substratum of such cases is a diffuse atheromatosis of the cerebral vessels, which causes a gradual destruction of the cortical representations of the facial, hypoglossal, and motor trigeminal nerves.

To produce a fairly complete analogue of the genuine bulbar type both cortices must undergo considerable destruction in the regions above indicated, with secondary changes in the cortico-bulbar projections. As these changes are all distinctly supranuclear, atrophy and electrical changes in the affected muscles are wanting.

Clinically, while the above picture is in the developmental stage, the patient is observed to have a series of mild shocks which differ in nowise from the ordinary. It is only when the cumulative effects of these various shocks are manifest in a bilateral paralysis or paresis of the muscles of the face, tongue, and jaws with accompanying disturbance of speech, swallowing, etc., that the resemblance to the bulbar paralysis begins. Even then the likeness is not complete, since severe disturbance of the respiration and of phonation is ordinarily absent.

The mental state of such patients differs markedly from that observed in the genuine form of bulbar paralysis in that some type of psychosis, or even dementia, is usually present. So-called bulbar crying and laughing is, on the other hand, commonly present, and may be very marked.

The paralysis is not necessarily limited to the face and tongue areas, so that hemiplegia or diplegia may be present.

A further type—the cerebro-bulbar—described by Oppenheim, differs from the above only in the fact that with the cerebral arterial break-down is associated a similar condition in the bulb. The lesions are never large and the bulbar symptoms are of gradual onset.

Symptomatically, bulbar phenomena are found associated with marked mental deterioration. Both bodily and mentally the patient is in a most deplorable state. With the usual disturbance of speech, mastication, and deglutition is associated spastic paralysis of the extremities on one or both sides. Attacks of dyspnœa and Cheyne-Stokes respiration either come on spontaneously or result from excitement, from paroxysms of spasmodic hiccough, or from attempts at motion. The optic nerves may undergo neuritis with consequent atrophy. The bladder and rectum may or may not be involved.

The prognosis in both the pseudo-bulbar and the cerebro-bulbar forms is very grave, although life may be prolonged for a considerable period of time.

The treatment recommended is that already described elsewhere.

Asthenic Bulbar Paralysis.

(Myasthenia Gravis Pseudoparalytica.)

To Erb (1879) is due the credit of calling attention to a symptom complex which so closely simulated that about to be described under asthenic bulbar paralysis that it must be considered its nosological analogue. It was not, however, until the appearance of Oppenheim's case in 1887 that this singular disease began to attract the attention which has been increasingly accorded to it up to the present moment.

Etiologically, little or nothing definite is known about it beyond the fact that it appears to result from the action of some toxic agent upon a congenitally predisposed nervous organism. Its association with tumors of the mediastinum and of the thymus gland has been noteworthy in specific instances. The predominance of the disease in early life is striking, but persons of advanced years are by no means exempt.

Pathology.—Up to the present time the most searching anatomic investigations have failed to reveal any organic changes in the medulla, bulbar nerves, or muscles. Congenital nervous defects and peculiarities have been observed in connection with certain cases, and a certain amount of stress has been laid upon the same as regards their morbid value, but it remains extremely doubtful if such stress has been rightly placed. The disease, in last analysis, appears to be a true neurosis.

Symptomatology.—This comprises the usual dysarthria, dysphagia, and masticatory weakness with their associated palsy of the lips, tongue, palate and jaw observed in the ordinary types of bulbar paralysis. Added to this is a paralysis of the upper part of the face with imperfect closure of the eyelids. The paralysis also extends to the trunk and extremities, and attacks of dyspnœa are frequent. In a certain number of cases the involvement of the eye muscles, notably ptosis, is the earliest and most striking symptom. Atrophy and reaction of degeneration in the affected nerves and muscles are absent throughout the entire course of the disease regardless of its duration.

Jolly in investigating the behavior of the affected nerves and muscles to electrical stimulation observed a peculiarity which he designated "myasthenic reaction." He found that where a tetanizing faradic current was applied (either to nerves or muscles) at intervals of a few seconds, the muscular contraction grew progressively weaker and gradually vanished completely, but that the muscle regained its irritability after a short rest. He further found that if the current were passed through a muscle without interruption for the space of a minute or even less, the muscular contraction gradually died away, but was again obtainable by the same sort of stimulation after a minute's rest.

Analogous phenomena have been observed in voluntary attempts to use the muscles of the jaw or extremities. A patient may take one bite of an article of food and then be totally unable to bring the jaws together with any force, but after resting a while may regain enough strength to chew for a few moments.

The course of the disease is very peculiar. The complete development of symptoms may require many months, although in certain cases the time required has been much briefer. Remissions are common, and the full development of symptoms may be followed by a regression, but so treacherous is the malady that when recovery seems fully established, there may be a fresh outbreak of the most rapid character and the symptom complex again be complete in a startlingly short time. Intercurrent attacks of dyspnœa and tachycardia and febrile movements are common.

The disease has on the whole so many peculiarities that differentiation is not difficult. The combination of bulbar symptoms with weakness of the muscles of the trunk and extremities, the frequent involvement of the external ocular muscles (manifested mainly by ptosis), the retention by the affected muscles of their normal volume, the absence of reaction of degeneration in the presence of the peculiar "myasthenic reaction" mentioned above, the characteristic tiring of affected muscles on voluntary motion, the lack of definite sensory and sensorial disturbance, the absence of mental weakness and disease, and the complete lack of any tangible pathologic substratum in the brain, nerves, or muscles unite to form a clinical and anatomical picture that is *sui generis*.

The PROGNOSIS is always serious. Nevertheless the most alarming cases may end in complete recovery. Recovery is, however, never assured until there has been a freedom from symptoms for a period of many months. to the present time the majority of cases have terminated Up fatally.

TREATMENT.—The proper care of this type of bulbar paralysis requires unusual skill. A complete rest treatment, such as is followed in the severest form of neurasthenia, should be carried out in bad cases to the minutest detail. The patient should be allowed to do almost nothing for himself, even to swallowing food, which, by the way, should be selected so as to combine the maximum of nourishment with the least tax upon the digestive organs. Even the use of the stomach tube for artificial feeding is not devoid of danger, as its introduction may induce fatal suffocation. If mastication can be permitted with safety in a given case, care should be taken to allow the patient to rest between mouthfuls.

The drug treatment consists in the administration of tonics. In certain cases the preliminary production of diaphoresis has been beneficial. Against the use of electrical stimulation it cannot be too strongly cautioned.

Joseph W. Courtney.

PRESCRIPTION-WRITING.—A medical prescription is a written order to the pharmacist to take certain quantities of certain medicines, deal with them in certain pharmaceutical ways, "put up" the product in certain form for dispensing, and label the package with certain directions for use. Correctness in prescribing, therefore, relates to the three several matters of the *selection of the ingredients* or *composition* of the prescription, the *fixing of quantities* or *computation* of the prescription, and the actual *writing of the order* in technical style, or *expression* of the prescription. These several topics will be considered *seriatim*, in the order named.

I. THE COMPOSING OF A PRESCRIPTION.—Assuming that a prescription is intended, as always should be the case, to fulfil a single therapeutic purpose only, then the first point that presents is whether, under the circumstances of the case, a *single* medicine of the appropriate kind should be prescribed, or a *team* of such medicines. As regards this point, no general rule can be laid down —the matter will depend partly upon the nature of the therapeutic indication, and partly upon the respective peculiarities of the individual drug and the individual case. Thus to provoke *emesis*, a single drug is commonly prescribed; to excite *diuresis*, a team; while for *purging* the medicine will be single, if it be castor or croton oil, but multiple, if the selection be from among the resinous cathartics. The advantage of a team of similar medicines in prescription may be, on the one hand, a more *effective*, or, on the other, a more *kindly* accomplishment of the specific purpose in view, or it may be both possibilities combined. Thus, by a wise association in prescription of allied drugs, a maximum of therapeutic effect is attainable with a minimum of by-derangement. Having fixed upon the active member, or team of members, of the prescription, the next point is whether the medicinal working of the same may not be made even more effective or more kindly than would otherwise be the case, by the further addition to the prescription of some special substance. Such increase in both lines—effectiveness and kindliness—may result by a chemical action upon the drug, on the one hand, or by a medicinal impression upon the system of the subject, on the other. Thus, as an instance of the working of a chemical action, stands the fact that the efficacy and kindliness of operation of a dose of *salicylic acid* are both enhanced by the addition to the acid of a solution of a sodic carbonate, whereby the salicylic acid, which under its own form is both insoluble and irritant, becomes the more soluble, and at the same time far less harsh, body, sodium salicylate. As instances of an associated medicinal impression by an unrelated drug affecting the operation of the active member of a prescription may be cited the rather mysterious enhancement of the diuretic action of digitalis by the associate action of calomel, and the neutralizing of the griping of the rougher cathartics by the associated antispasmodic action of the pungent volatile oils, or of neurotics, such as belladonna or hyoscyamus. In the category of additions to a prescription for the purpose of enhancing *kindliness* of operation, belong *flavoring* substances. For an agreeable, or, at least, a not offensive potion, is not merely *pleasanter* than an ill-tasting one to swallow, but is also, by the very reason of non-offensiveness, far less likely than a nauseous dose to destroy appetite or derange digestion. The art of prescribing pleasant mixtures is therefore one of genuine advantage to the patient, as well as to the prescriber! Agreeability of taste is, of course, far more important in the case of fluid than of solid mixtures, and is attained, in the case of fluids, in part by wisdom in the selection of the active member of the prescription, and in part by the addition to the prescription of *sugar*, or of *syrup*, or of preparations of the more pleasantly flavored *aromatics*. Lastly, in composing a prescription, comes the thought of a possibly necessary substance to give *volume*, or, in the case of a powder or pill, to give *form*, or, in the case of a fluid mixture, to serve as a diluent, or as a solvent. The character and relative proportion of such a member of a prescription will vary so greatly in different cases, that no general rule affecting the selection of vehicles can be formulated. Members of a prescription for the several purposes named are commonly referred to as, respectively, the *basis*, the *adjuvant*, the *corrigent*, and the *excipient*, or *vehicle*, of the prescription. In the association of different substances in a prescription, no matter what the purpose of the several ingredients, regard must always be had for the mutual *chemical* relations of the things so brought into mutual contact, lest undesirable reactions take place in the compounding (see *Incompatibility, Medicinal*).

II. The Computing of Amounts in Prescriptions.—The first point in the matter of amounts in prescriptions is, in general, *not to order more of the medicine than present prognosis seems to call for.* Not unnaturally, the laity instinctively argue that the remedy should fit the case in *measure* as well as in *mode*, and hence, that an excess of medicine in the prescription is *prima-facie* evidence of a deficiency of skill on the part of the prescriber. They, furthermore, naturally object to the *paying* for the superfluous. Apart from these considerations, there are also many and obvious objections to a course that leaves half-used parcels of medicine to accumulate in a house, at the risk of inappropriate application on subsequent occasions, at ignorant hands. Hence, in cases in which an exact forecast of the amount of a medicine likely to be required is impossible, it is wiser to order no more than will surely be within bounds, letting the prescription be renewed if the amount prove too little. Assuming due regard to be paid to this principle, then the determination of amounts in a given prescription proceeds, by theory, thus: the amount of *basis* will be the product of the two factors, *quantity of dose* and *number of doses* required, and the several amounts of the other ingredients will be deduced from the amount of the basis, in accordance with the respective requirements of relative proportion. In putting this theory into practice, however, the important consideration has to be regarded, that quantities must be such as can conveniently be expressed in terms of the system of weight or of measure employed in the prescribing. This consideration determines, in general, the use of *round numbers*, and, in particular, of *such* round numbers as best conform to the relation between denominations in the particular system of weight or of measure followed in the prescription. For example, in general, no prescriber would fix a dose to be expressed by such a number as *one and one-tenth*, whether referring to grains or grams, nor would he ever estimate upon an aggregate of such an awkward number of doses as *seven*, or *eleven*, or *nineteen*, or *twenty-three*. And, for example again, in particular, the prescriber by the *apothecaries'* system of weight or of measure, recognizing the generally *duodecimal* ratio of the denominations of these scales, instinctively proportions the numbers of his prescription on a *duodecimal* basis. His ratios, that is, are as one to some one of the numbers 2, 4, 6, 8, 12, 18, 24, 60, 120, 180, 240, 480. On the other hand, if the *metric* system be the system followed, the *decimal* basis of this system almost of necessity entails the use of decimal ratios in proportioning amounts in prescription. Quantities are in this case fixed upon that are to each other as one to some number of this series of numbers: 2, 5, 10, 20, 25, 50, 75, 100, 200, 250, 500, 1,000. This fundamental difference in the figures to be used in working by the metric system as compared with the apothecaries' is a point very commonly overlooked by novices, in this country, in the art of prescribing by metric denominations. Because already fixed in the duodecimal habit through previous practice with the apothecaries' system, such novices are apt to compute in *duodecimal* ratios quantities which they then set down in terms of *decimally* related denominations—a proceeding wherein theoretical stupidity begets, as it should, practical disaster. For, by this proceeding, as it is hardly necessary to point out, there is wholly missed the one point of advantage which the metric system has to offer, namely, ease of computation by *decimal ratios*. A medicine, then, whose dose in prescription by apothecaries' weight is taken at *one grain*, is—or should be—in prescribing by metric weight, taken at *five* centigrams, and not at the *six* centigram amount by which the American metric prescriber, translating from terms of apothecaries' weight, so commonly figures. As well might an original metrician—to coin a convenient word—who essays a prescription by the apothecaries' system, first fix his dose, by his old metric habit, at five centigrams, and then, blindly insisting on exactly that quantum, despite its unsuitableness to the foreign system of weights, prescribe in grains on the absurd basis of a *seven-eighths-grain* dose!

Such are the essential points of the theory of computing prescription amounts, and having due regard to these points, the prescription of *solid* mixtures for make-up into pills, powders, troches, suppositories, etc., is easy enough; but in the prescription of *fluid* mixtures many additional considerations enter into relation, as follows: In the first place, although it is not essential, yet it is elegant, and hence customary, to have a prescribed mixture aggregate *just a bottleful* of some one of the sizes of the medicine phials of the shops. Regard must therefore be had to the several sizes of such bottles. In the United States medicine phials are made of capacities conforming to *apothecaries' measure*, which capacities are severally as follows: *one*, *two*, and *four fluidrachms*, and *one*, *two*, *four*, *six*, *eight*, and *twelve fluidounces*. This fact of the conformity of medicine bottles to apothecaries' measure, makes, in this country, the prescribing of fluid mixtures readier by the apothecaries' than by the metric system. Phials for metric prescription should be of the natural metric capacities, severally, of *twenty-five*, *fifty*, *one hundred*, *two hundred*, etc., *cubic centimetres*.

The second special point affecting amounts in the case of fluid mixtures relates to the case of solids in solution, the point being the physical fact that, in dissolving a solid of a given measure in its condition of dry powder *does not augment the volume of the solvent by the full amount of such measure*, but, on the contrary, increases such volume so little that, in the ordinarily comparatively weak solutions used as medicines, the increment can safely be disregarded in the estimation of amounts for prescription.

The third point relates to the system by which, in a given case of a fluid mixture for internal giving, the *individual doses are to be measured*. This consideration does not obtain in the case of solids, since, in such case, doses are defined by a stated number of pills, powders, or troches—are, that is, already apportioned by the apothecary. But in the case of a fluid mixture, the medicine is necessarily dispensed in bulk (except when put up in capsules), and doses must be measured out by the administrator at the bedside. The point then presents itself of practical bearing, whether, in a given case, the dose is to be measured by a method of precision—by use of a graduated pipette, if the dose be quite small, or of a graduated vessel if of ordinary or large dimension—or whether the determination is to be by the conventional *drop* on the one hand or *spoonful* on the other. If a graduate is to be used, then the point now in question does not present itself; but if the *drop* or the *spoonful* is to measure the dose, then the consideration arises, in the apportioning of amounts in prescription, of the respective actual *dimensions* of these variable measures, under the conditions obtaining in the individual case. As regards the *drop*, it must be remembered that this measure varies in dimension, not only according to the viscosity and specific gravity of the fluid dropped, but also according to the *shape*, *extent*, and *character* of the surface from which the drop delivers itself, and even, furthermore, in the case of drops delivered from a phial, according to the *degree of fulness of the bottle* on the occasion of the dropping. A bottle with a flanged mouth, such as the ordinary medicine phial, yields, with the same fluid, a comparatively large drop when full or nearly so at the dropping, and a comparatively small one when at least half empty, the difference in the respective drop dimensions in the two instances being even as considerable as that between the numbers five and three. The reason for this difference in size of drops is that, from a full bottle, the contents begin to run out when the bottle is but slightly tipped, and accordingly, because of the position of the free edge of the lip, the nascent drop creeps into the re-entrant angle formed by the under surface of the lip and the side of the neck, and there has a chance to grow to a comparatively goodly size before gravity determines the fall. On the other hand, a phial half empty must be tipped to the horizontal before the contents can run out, in which position the narrow rim of the lip points directly downward, and so presents but a small surface area for the fluid to cling to. Under these circumstances the fall will necessarily be in comparatively small drops. As regards the *spoonful*, it must be remembered that this measure, like the drop, is subject to variation, so that, in the case of prescriptions containing powerful medicines, amounts should be calculated on the basis of the *maximum capacity of the measure*. Whatever, then, may be the variation from the calculated dose in actual mensuration, will be on the safe side of a *shortage* instead of a possible *excess* of amount. Now a given spoon will naturally hold more of a *viscid* than of a *thin* fluid, and, in practical mensuration, will more readily hold its full complement when the fluid is poured *into* it, as from a bottle, than when the spoon is made to dip up the fluid from an open vessel. Hence, in the case of a *syrupy* mixture, with the dose to be taken *directly from the phial*, the conditions obtain where the spoonful will be at its maximum; while, on the other hand, in the instance of a thin watery dilution standing in a tumbler, with the dose to be dipped up by means of the spoon, the measure, although the same in name, may be very different indeed in fact. Another point, which should thoroughly be understood, relates to the size of the average spoon of to-day as compared with the spoon of the same denomination of two generations ago. Coming down from our ancestors is the estimate of the *tablespoonful* as the measure of half a fluidounce, or 16 c.c., and of the *teaspoonful* as that of a fluidrachm, or 4 c.c. These alleged equivalences, true of the average of spoonfuls of former days, are still handed down as present truth from teacher to student, and so come to be almost universally applied in prescription calculations. If, however, the reader will take from any chance pantry a sample of the average commoner kind of teaspoon, such as is generally relegated for service in the nursery, and will provide for himself an accurate graduate and a phial of water, he can learn for himself, in two minutes, the fact that the teaspoonful will run much nearer *six* to the fluidounce than the traditional *eight*—will equal the quantity of *five* rather than of *four* cubic centimetres. And, by the same token, the average tablespoonful of our own present spoons is of the dimensions of *three* rather than of *four* to the two-fluidounce measure—of *twenty* rather than of *sixteen* cubic centimetres. And indeed, in the case of thick fluids, such as strongly syrupy mixtures, or a fixed oil like castor oil, where also the fluid is poured into the spoon, the spoonful will considerably exceed even these larger estimates. In view of these facts, this writer, in his teaching, has always advised for prescription purposes the estimate of the equivalence of the teaspoonful as at 5 c.c., or at the rate of six to the fluidounce; and of the tablespoonful at 20 c.c., or at the rate of three to two fluidounces—six to four fluidounces.

By basing calculations on such assumed equivalences, any error in actual mensuration will be, as it should be, in the direction of a measure smaller rather than greater than intended. Furthermore, it is a happy fact that these equivalences give numerical relations far handier for purposes of calculation than the older estimates. In the case of the metric values, it goes without saying that for computation in decimal denominations, the numbers *five* and *twenty* are much more convenient for expressions of respective unit quantities than the numbers *four* and *sixteen*. And in the apothecaries' system the proportion of six to the fluidounce permits of a greater number of easily calculated combinations than the time-honored eight to the same measure, as is shown in the tables below.

A fourth consideration affecting the estimation of amounts in the prescription of fluid mixtures, obtains in the prescribing of a solid to be borne in solution in an inert fluid menstruum, the point being the matter of the proper proportion between solid and solvent. Of course, in the first place, the proportion must be compatible with the solubility, in the selected menstruum, of the given solid; and, also of course, in the second place, if the dose is to be diluted extemporaneously for the taking, the concentration of the prescribed solution may be to any degree so compatible with solubility. If, however, as so often is the case, the prescription purposes a solution fit for direct administration without further dilution, then the consideration of *taste* enters into relation. An over-strong solution will be rough to the taste, and may also be irritant or even corrosive to the alimentary mucous membranes; while, on the other hand, if the solution be inordinately weak, the volume required for the carrying of a proper dose of the dissolved basis may be inconveniently large. Of course, in this matter the individual peculiarities of the constituents of a given prescription will require individual consideration; but, in a general way, the truth obtains that the *teaspoonful* is best made the carrier of not more than—in convenient round numbers of the respective systems of weight—*twenty-five centigrams*, or *five grains*; and, similarly, the *tablespoonful* of not more than, respectively, *one gram*, or *twenty grains*, of a solid in solution. In the case of fairly bland substances, whose solubilities will at the same time permit, twice these quantities may be permissible; but such proportion should not be exceeded.

From this presentation of points affecting the prescription of fluid mixtures, it appears that, in cases in which it is expected that the whole bottleful is to be used, the estimate of amounts must harmonize a trio of conditions as follows: (1) The total must be just a bottleful; (2) it must aggregate *about* the number of doses therapeutically indicated; and (3) at the same time the amount of the active basis, while being such as to yield the proper strength of solution, must also be such as to admit of ready expression in terms of the system of weight or measure employed in the writing. In the use of the metric system this triple harmonization presents no difficulties, for the simple reason that since *any* amount is equally easy of expression by this system, it is only necessary to harmonize the first two considerations, letting the amount of active basis required foot up to what it will. Thus, for instance, let it be supposed that an indication seems to call for a medication three times a day for a few days; then all it is necessary to remember is that, if the active basis be one of small dose such that a teaspoonful is the more convenient carrier, a *fifty cubic centimetre* aggregate will fulfil the conditions of an even bottleful on the one hand, and about the requisite number of doses upon the other (ten teaspoonfuls, reckoning the teaspoonful at 5 c.c.). Then the individual dose of basis may be taken unconditionally by the therapeutic indication—it may be fixed at one, two, three, four, five, six, seven, eight, nine, ten, or any odd number of centigrams, and the expression of the aggregate will be equally easy, such aggregate being simply ten times the quantity for the individual dose, respectively, as follows: 0.10, 0.20, 0.30, 0.40, 0.50, 0.60, 0.70, 0.80, 0.90, 1.00 gm., etc. Similarly, if the case be one where a *tablespoonful* will be the more convenient measure for the dose, then a *two hundred* cubic centimetre volume will again yield ten doses (about the number indicated) of the selected dimension, and once more the individual dose of basis may be what it please, and the aggregate will be equally easy of expression. When, however, the *apothecaries'* system is followed in the prescription, at once a complication arises, for the reason that in apothecaries' weight all amounts are *not* equally easy of expression—some, indeed, being so awkward to express as practically to be unavailable. Thus, for instance, although by this system, as already pointed out, ratios are naturally taken in duodecimals, yet such a natural duodecimal multiple as *seventy-two*, representing grains, is a monstrosity for expression. In computing, therefore, by apothecaries' weight and measure, the prescriber is bound by the clumsiness of the denomination ratios of the system, and so, for cases in which the total basis exceeds a drachm, finds available for the fulfilment of the tripartite conditioning set forth above, a certain set of combinations only. These combinations the young prescriber must learn by rote. They are easily enough figured out for one's self;

but for convenience of reference there are set forth, in tabular form below, the combinations convenient when the individual dose of basis is to be one or other of the several amounts, *five*, *ten*, *fifteen*, or *twenty* grains. If the individual dose of basis be *less* than a grain or two, then the total amount of basis required, being but a *moderate number of grains*, is easy enough of expression, and the difficulty now under consideration does not obtain.

Table of Convenient Combinations for the Prescription of Fluid Mixtures by Apothecaries' Measure and Weight.

1. *Dose to be borne in an average teaspoonful, reckoning six teaspoonfuls to the fluidounce.*

Capacity of phial in fluidounces.	Number of teaspoonfuls contained.	Amount of Basis to be Prescribed in Order to Yield to the Teaspoonful the Several Doses of—			
		Five grains.	Ten grains.	Fifteen grains.	Twenty grains.

12	24	ʒ ij.	℥ ss.	ʒ vi.	℥ i.

III. The Expressing of a Prescription.—A prescription is an order, *dated* and *signed*, to the pharmacist to take certain quantities of certain several substances; to perform upon them certain pharmaceutical operations; to label the package with certain directions concerning use, and to address it with the name of the patient. Upon this order the author may also have occasion to set down certain injunctions, such as "not to be renewed," or, "not to be shown to the patient," etc. In *form*, prescriptions are commonly written after the following paradigm:

[*Not renewable without authority.*]

For Mr. A. B.

Take
Of substance *A*, quantity *x*.
Of substance *B*, quantity *y*.
Of substance *C*, quantity *z* [etc.]
Do so-and-so [with them]..........................
Label [the package]..............................
[*Signed*] C.D., M.D.,
No. 1 Blank Street.
[Dated] November 22d, 1886.

Instead of a written signature, a very common and a very good plan, followed by many practitioners, is to have prescription blanks printed for their personal use, bearing the imprint of name, address, and office hours. In such case the imprint is commonly at the head of the paper. In *language*, a prescription is commonly written in part in Latin, and in part in the vernacular. In the United States the use of the Latin is commonly confined to such portion of the prescription as has to do with directions to the pharmacist for the compounding and "putting up" of the medicine; but in many other countries the *directions for use* are also written in Latin. This latter foreign custom has nothing to commend itself, but, on the contrary, is intrinsically objectionable on the score of opening an unnecessary doorway for the entry of mistakes. For such directions must, of necessity, finally appear in the vernacular in the label upon the package which is to serve for the patient's guidance; so that, to write them in the prescription in Latin is to entail their translation back into the vernacular at the hands of the pharmacist for the purpose of transcription, all at the risk of mistakes. Far better is the American custom, whereby the prescriber can—and always *ought*—set down, in the vernacular, in *full necessary detail*, the directions for administration, which directions are then simply to be copied, *exactly as written*, in the labelling of the package. Another, and quite universal, custom is to express by *abbreviation* or by *symbol*, in the pharmaceutical portion of the prescription, what might be called *staple* words. Thus, in the foregoing paradigm, *take* is expressed by the symbol "℞," which, originally the astronomical sign "♃," of the planet Jupiter (symbolical of the prayer to the deity Jove which in ancient times headed prescriptions), now bears its present peculiar form in order to do duty also as the initial letter of the Latin word *recipe*, signifying *take thou*. Next, titles of denominations of weight or measure are expressed by the commonly employed symbols for such denominations, and numeral adjectives by the so-called *Roman* numerals in the use of the *apothecaries'* system of weight or measure; but by the ordinary *Arabic* numerals when the prescription is by *metric* weight or measure, as is practically a necessity for the expression of the related integral and decimal fractions by which metric quantities are signified. Next, the word *misce*, signifying *mix thou*—the most commonly occurring word expressing requirement of pharmaceutical manipulation, is expressed by its initial letter *M.*, and similarly, and lastly, the word *signa*, signifying *label thou*, by its initial letter *S.* Other commonly employed abbreviations are "āā" for *ana*, latinized Greek for the phrase *of each*; "no." for *numero*, signifying *to the number of*; "q. s." for *quantum sufficiat*, signifying *as much as may be necessary*, and "p. r. n." for *pro re natâ*, signifying *according to need*.

It thus appears that all of the prescription requiring full dress in Latin is comprised in the titles of substances prescribed, and in the directions for the compounding. And for the correct latinizing of such items a critical knowledge of the Latin language, though, of course, of great advantage, is yet not indispensable. For, so far as relates to the expression of *medicine-titles*, all that is necessary is to know how to set these titles in proper *case*;

and, as concerns the expression of *pharmaceutical directions*, it is to be remembered that, in the great majority of instances, the directions for compounding requiring specification in prescription writing, are simple and set, so that their Latin phrasing is easily compassed by the knowledge of a few arbitrary words and phrases. Indeed, for all but seldom occurring exceptional directions, the latinizing can be effected by the words and phrases in the following list, properly coupled with Latin words signifying forms of medicines, presumably already learned.

List of Odd Words and Phrases of Common Occurrence in the Expression of Pharmaceutical Directions, in Prescriptions.—1. *Verbs*, in *imperative mood;* "object" to be in the *accusative* case (analogue of the English *objective*):

Ádde, add.
Cóla, strain.
Dívide, divide.
Exténde, spread.
Fac, make.

Fíltra, filter.
Mácera, macerate.
Mísce, mix.
Sólve, dissolve.
Tére, rub.

2. *Verbs*, in *subjunctive mood*, taking a *subject* or a *predicate, nominative:*

Búlliat, let [it] boil.
Fíat, let [*it*] be made [into].
Fíant, let [*them*] be made [into].

3. *Verbal adjective* (participle) to agree with its noun in gender, number, and case:

Dividéndus (masculine); *-a* (feminine); *-um* (neuter), to be divided.

4. *Prepositions:* noun following to be in the *accusative* case:

Ad, to; up to. *In*, into. *Súpra*, upon.

5. *Prepositions:* noun following to be in the *ablative* case:

Cum, with. *Pro*, for.

6. *Miscellaneous Words and Phrases:*

Ána, of each.
Béne, well.
Bis, twice.
Déin or *deínde*, thereupon.
Et, and.
Gradátim, gradually.

Guttátim, by drops.
Non, not.
Sémel, once.
Símul, together.
Státim, at once.
Ter, thrice.

In the instance of a pharmaceutical operation which cannot be expressed in Latin by the application of the foregoing vocabulary, the wise course, even for the Latin scholar, is to forego elegance and write the direction in the vernacular. Otherwise it might chance that the prescription overstep the pharmacist's capacity for translation, to the obvious defeat of the compounding.

As regards the rendering, in proper Latin case, of the titles of the ingredient substances of a prescription, the points are as follows: There are, in Latin, six cases in the declension of nouns and adjectives, but of these cases four only are concerned in the latinizing of medicine titles. These four are, respectively, as follows: The *nominative* case, corresponding to the English nominative, is the case in which titular words stand in simple statement—by which, in short, names are learned. Thus we recognize prepared chalk by the Latin title *Creta præparata*, wherein the two words of the title are in the nominative case. Next, the *genitive* case corresponds to the English *objective* case after the preposition *of*, and is the case in which titular words most commonly stand in prescription writing. For, in the first place, *compound* titles, even in simple statement, commonly afford an instance of the genitive, as in the case of the title *tincture of opium*. Here the phrase *of opium* is rendered in Latin by the word *opium* set in the genitive case. Then, in the second place, in prescribing, the order for the "taking" of a given ingredient is, in the enormous majority of instances, a direction for the taking of a specified *quantity* of the substance in question. A prescription for a phial of laudanum, that is, will read: "Take *of* tincture of opium one-half fluidounce." In such case the titular word of the preparation itself—in this instance the word *tincture*—will have to stand in the genitive, since now it, also, follows the preposition *of*. With the exception, therefore, of a few conditions when titular words stand, in prescription expression, in the *accusative*, the rule is that all titular nouns and adjectives which, in simple statement of the title, stand in the *nominative*, require, in prescription orders, to be set in the *genitive*.

The third Latin case that concerns the prescriber is the *accusative*, the Latin analogue of the English *objective following a transitive verb*. Titular nouns and adjectives take the accusative under the two following circumstances: First, when the order is not the common one to take a certain specified measure or weight *of* the thing, but to take *the thing itself* in a conditioned entirety. A common instance of this circumstance is where yolk or white of egg is an ingredient of a prescription. Here by the condition of things it is easiest to measure quantity by the natural measure of the egg substance itself. Hence, in prescribing yolk the order is commonly to *take the yolk of one egg*, or of two, or of three eggs, as the case may be; in which case the title word *yolk*, standing as the direct object of the transitive verb *take*, requires to be put in the accusative. Another commonly occurring instance where the accusative must appear, is where the prescriber writes for a certain *number* of a ready-made medicinal *entity*, such as pills or troches, of standard composition, and hence of independent title. Thus, to prescribe the pharmacopœial *compound cathartic pill*, the simplest way is to order directly the desired *number* of the already made pills, which the pharmacist keeps in stock. Such prescription, therefore, reads: "Take compound cathartic pills to the number of" so many, and so the word for *pills*, with its dependent adjectives, appearing as the immediate object of the verb *take*, stands in the accusative. The second circumstance determining the setting in the accusative of titular nouns and adjectives occurs, in one form of writing, in cases in which the prescription orders that a given substance be taken *up to the attainment of a certain total bulk or weight*. This form of order most commonly obtains in the prescription of fluid mixtures, where it is often convenient to order in specified quantities the necessary amounts, respectively, of basis or adjuvant; but, as regards the inert *vehicle* simply to direct the compounder to "take" the vehicle substance until the whole mixture shall attain the measure of the desired bottleful. In such case the order for the vehicle may be phrased in either of two styles—in the one of which the titular words will appear as usual in the genitive, but, in the other, in the accusative. The phrase in the latter style is according to the model, *take so-and-so up to* [*the measure of*] *so much*. Here the title of the substance "taken" is the immediate object of the verb *take*, and therefore stands in the accusative; the phrase *up to the measure of* being expressed by the preposition *ad*. The other style of phrasing the order is after this model: *Take of so-and-so as much as may be necessary to attain the measure of so much*. Here the title of the medicine once more follows the preposition *of*, and hence appears in the genitive. In the rendering of the order in this style, the Latin phrase *quantum sufficiat ad* (commonly abbreviated to *q. s. ad*) is the translation of the English "as much as may be necessary to attain the measure of."

The fourth and last Latin case that concerns the prescriber is the *ablative*, a case corresponding to the English objective after certain prepositions. The prepositions governing the ablative that occur in prescription writing are *cum*, "with," and *pro*, "for." The former of these occurs in a few titles, as for instance, *Hydrargyrum cum Cretâ*, mercury with chalk; *Emplastrum Picis cum Cantharide*, pitch plaster with cantharides; and the latter in the much-used phrase *pro re natâ*, "according to need." But as regards the ablative, the special point obtains that the circumstances of prescription phrasing never require the rendering in the ablative of a title word which in the title appears in a different case. The few instances of the ablative in medicine titles are therefore fixed, and the ablatives so occurring are easily learned by rote.

The *expression* of case is, in Latin, effected by modification of the ending of the word itself which is to be declined, and in such modification, *adjectives* share as well as nouns. Different modifications are employed to signify case in the singular and plural number, respectively, and of such modifications there are, in ordinary, five distinct systems, constituting the five several *declensions* of nouns and adjectives, besides cases of irregular declension presented by certain pronouns and cardinal numerals. Of the five systematic declensions, one, the *fifth*, affords but a single example in prescription Latin, namely, the ablative *re* of the noun *res* in the oft-quoted phrase *pro re natâ*. Of the other four declensions, examples occur in prescription-writing of the *nominative*, *genitive*, *accusative*, and *ablative* cases, respectively, in the singular number, and of the *nominative*, *genitive*, and *accusative* in the plural. The following table shows the endings for the several cases so enumerated, so far as concerns nouns and adjectives embraced in the prescriber's vocabulary. Endings for nouns not in such vocabulary are purposely omitted, as are also the irregular declensions of pronouns. In the table the italicized letters *m.*, *f.*, and *n.*, signify respectively, that the case endings in the columns beneath are those of nouns or adjectives of the *masculine*, *feminine*, or *neuter* gender; for, as appears in the table, case endings often differ, even in the same declension, according to the gender of the word. The endings of the first and second declensions, severally, which appear *in parenthesis*, are the endings of certain Greek nouns, adopted into Latin with something of the Greek form retained. The table also gives a list of words of foreign origin applied as drug titles, which, following the Latin idiom in such case, make no change of ending to signify case—are, in short, *indeclinable*.

TABLE OF PARTS OF LATIN DECLENSIONS SO FAR AS EXEMPLIFIED BY WORDS USED IN PRESCRIPTION-WRITING.

1. *Regular Declensions of Nouns and Adjectives.*

	First declension.	Second declension.		Third declension.		Fourth declension.
	f.	*m.**	*n.*	*m. and f.*	*n.*	*m.*†
SINGULAR.						
Nominative	-a (-e)	-us (-os)	-um (-on)	(various)	(various)	-us
Genitive ...	-æ (-es)	-i		-is		-ûs

PLURAL.						
Nominative	-æ	-i	-a	-es	-a	-us
Genitive ...	-arum	-orum		-um, -ium		-uum
Accusative .	-as	-os	-a	-es	-a	-us

(Fifth Declension exemplified only in ablative singular *re* in phrase *pro re natâ*.)

* Except *juniperus*, *prunus*, *rhamnus*, *sambucus*, and *ulmus*, feminine.

† Except *quercus*, feminine.

2. *Declension of Cardinal Numerals.*

	Unus, One.			*Duo*, Two.			*Tres*, Three.	
	m.	*f.*	*n.*	*m.*	*f.*	*n.*	*m. and f.*	*n.*
Nominative	un-us	-a	-um	du-o	-æ	-o	tr -es	-ia
Genitive ...	-ius			-orum	-arum	-orum	-ium	
Accusative .	-um	-am	-um	-os	-as	-o	-es	-ia

All other cardinal numerals are indeclinable.

INDECLINABLE DRUG-TITLES—*all neuter.*

Alcohol,
Amyl,
Buchu,
Cajuputi,
Catechu,
Chloral,
Cusso,
Elixir,
Eucalyptol,
Kamala,
Kino,
Matico,

INDECLINABLE DRUG-TITLES—*all neuter.*—*Continued.*

Menthol,
Methyl,
Naphtol,
Pyrogallol,
Salol,
Sassafras,
Sumbul,
Thymol.

As appears at a glance from the foregoing table, in the case of any noun or adjective belonging to either of the three declensions numbered as *first*, *second*, and *fourth*, respectively, if the *nominative* be given, any other case can at once be formed by substituting the proper case ending for that of the nominative. In words of the *third* declension, however, this possibility in very many cases does not obtain. For in this declension the *nominative* often stands apart from the other cases in the way of having the very root, or "stem," of the word curtailed or modified in its construction. Thus, the stem *anthemid-*, giving genitive *anthemidis*, accusative *anthemidem*, and ablative *anthemide*, gives nominative *anthemis*—a word in which the full stem does not appear. Similarly, the root *flor-*, giving genitive *floris*, etc., gives nominative *flos*; and root *rho-*, giving genitive *rhois*, offers the much modified nominative form *rhus*. Hence, for the proper rendering in oblique case of nouns or adjectives of the *third* declension, it becomes necessary to learn arbitrarily the form of some one of the oblique cases—most conveniently the genitive—as well as that of the nominative.

A special point concerned in the expression of case obtains in the case of *adjectives*, to the effect that very many of these words form their case endings after different ones of the declension models, according to the *gender* of the noun to which the adjective is attached. In compound drug titles, therefore, which include an adjective, the gender of the noun modified by the adjective becomes necessary to know for the *intelligent*, proper rendering of the adjective's case ending. Of course, such knowledge is not essential, since the title, adjective, and all, can be learned by rote, and then, remembering the nominative form of the adjective, the necessary change to genitive or accusative, to suit the requirement of the prescription phrase, can be done by rule. But it saves a vast amount of unnecessary memorizing to understand the system, so far as system goes, by which genders of Latin nouns are determined. Reverting, then, to the above declension table, it appears that all prescription occurring nouns of the *first* declension are *feminine* in gender; all those of the *second* declension ending in *-um*, or *-on*, are neuter, and, with a few exceptions, all of the *second* declension ending in *-us*, or *-os*, and all of the *fourth* declension ending in *-us*, are *masculine*. The exceptions in the two latter instances are nouns in *-us*, representing ancient Latin *tree-names*, which, because of the ancient Latin conception of an inherent femininity in trees as things, take the feminine gender in spite of their etymologically masculine nominative ending. In the *third* declension all genders appear, and, although in nouns of certain nominative endings the ending carries with it the gender, yet in the case of many other nouns this is not so, and genders must be learned arbitrarily. Happily, however, the number of nouns of the third declension, among drug titles, which bear an associated adjective, are quite few.

From the above analysis it is evident that, in the case of a given *noun* in the nominative, the rendering of the same in an oblique case can proceed by rule according to the foregoing declension table, if only the declension of the noun be known; with the further item, in the instance of a noun of the *third* declension, that some one oblique case, as well as the nominative, be known, for the affording of the full stem of the word. Similarly, the proper case dress of any given *adjective* can be fixed if the scheme of declension of the adjective itself be known, on the one hand, and, on the other, the gender of the noun to which the adjective is to be affixed—adjectives requiring to agree with their respective nouns in gender, number, and case. This requisite information concerning nouns and adjectives of prescription use is afforded in the two following tables—the one giving a key to the declensions of nouns, with genders, and also, in the case of nouns of the third declension, genitive endings—and the other showing the schemes of declension of adjectives.

Table showing Declension and Gender of Nouns Occurring in Titles of U. S. Pharmacopœial Medicines and in Common Prescription Terms.

Nominative singular ending in **-a:**

All First Declension and Feminine, except (of Greek origin) *the following* in *-ma:*

Physosti'gma (physostig'matis), 3d, *n.*
Aspidospe'rma (aspidospe'rmatis), 3d, *n.*
E'nema (ene'matis), 3d, *n.*
Catapla'sma (catapla'smatis), 3d, *n.*
Gargari'sma (gargari'smatis), 3d, *n.*
Theobro'ma (theobro'matis), 3d, *n.*

Nominative Singular ending in **-us:**

All Second Declension, Masculine, except—

Juni'perus, 2d, *f.*

Table showing Schemes of Declension and Gender of Adjectives Occurring in U. S. Pharmacopœial Medicinal Titles and in Prescription-phrases.

Scheme I.—*Second and First Declensions Combined.*

Masculine.	*Feminine.*	*Neuter.*
-us [2d dec.]	*-a* [1st dec.]	*-um* (*-on*) [2d dec.]

Scheme II.—*Third Declension.*

Masculine and Feminine.	*Neuter.*
-is (genitive *-is*).	*-e* (genitive *-is*).

Scheme III.—*Third Declension.*

Masculine and Feminine.

-or (genitive *-oris*).

Scheme IV.—*Third Declension.*

All Genders.

-ens (genitive singular *-entis*); (genitive plural *-entium*).

In commentary upon the declension schemes of adjectives set forth in the foregoing table, it may be stated that Scheme I. embraces by far the greater number of adjectives. In this scheme the neuter ending *-on*, borrowed from the Greek like the same ending among nouns of the second declension, finds among drug titles but a single example, *diachylon*. Scheme II. embraces a few adjectives only among those occurring in medicine titles, and affords an example of the nominative ending *-e* of the third declension, which does not occur among *nouns* of pharmacopœial titles. Scheme III. offers a single example only, viz., *fortior*. Of Scheme IV. pharmacopœial adjectives give but two examples, namely, *effervescens* and *recens*. A survey of the *genders* marked on the table shows that in every case a distinctive gender, where there is such, can be told from the adjective nominative ending.

A final point, concerning the expression of a prescription, is that, having regard to the fact that a *slip of the pen* on the part of the writer, or a *slip of the understanding* on the part of the pharmacist reader of a prescription, may convert what was meant as a missive of mercy into a death warrant, it behooves the prescriber most solemnly to execute his task *deliberately*, *thoughtfully*, and, in chirography, *legibly*, *abjuring all dangerous cloak-of-ignorance abbreviation of medicine-titles;* and, finally, to fail not of that trusty safeguard against error, a *review of the paper* after the writing.

Edward Curtis.

PROTOZOA.—Standing distinctly as the lowest of all animal organisms, the protozoa constitute a branch differentiated from higher groups by the simplicity of organization in that the animal consists of but a single cell or a colony of simple cells. In the main the animals of this group are easily recognized, although some forms are so generalized, and partake of plant characteristics to such an extent as to render their classification doubtful; and, on the other hand, certain higher forms show the first stages in specialization among cells of the colony which ultimately leads to the differentiation of the metazoan organism.

The Protozoa are true cells and possess consequently neither organs nor tissues. In the discharge of all living functions by the single cell, however, one finds a physiologic complexity as striking as the morphologic simplicity. The latter is also less extreme in many cases where specialization has effected the production of individual features within the single cell, differentiations which subserve particular functions, and which are thus analogous to the organs of the metazoa. Such are denominated cell organs, or organellæ, and are of great variety. Among these may be mentioned the locomotor structures, such as pseudopodia, flagella, and cilia, the numerous vacuoles of a nutritive and contractile type, the preformed, often highly modified openings for ingestion of food and egestion of solid waste matter, and various protective coverings of a permanent character or temporary and connected with reproduction.

As true cells all Protozoa possess one or more nuclei, and the earlier contention that there exists a special group of anuclear organisms, the monera of Haeckel, has not been confirmed by later study. The simple protozoon is with a single known exception (*Loxodes rostrum*) uninuclear, and the presence of many nuclei points to a colonial organism or to a reproductive phase, except that in one large group two forms of nuclei coexist and divide the functions otherwise resident in the single nucleus.

The reproduction of the Protozoa is again that of the cell, viz., by division, which may be simple or multiple, and in varied form, either while free or in the encysted condition. Two types of division may alternate regularly or indefinitely in the life cycle of a given species, and in most subdivisions of the group certain so-called sexual processes have been demonstrated. These consist in general in the fusion of similar individuals (isogametes), or of dissimilar (macro- and microgametes), or merely in the mutual exchange of nuclear matter.

In regard to location parasitism among the Protozoa affords conditions not found otherwise. There are in this group not only organ parasites, as in the groups of helminthes, but also such forms as must be designated tissue parasites, cell parasites, and even nuclear parasites. Different phases in the life cycle of the same species may illustrate different modes of parasitism, as is the case with the malarial organisms, which at various epochs in the life history are successively cell parasites in the erythrocytes, organ parasites in the blood-vessels, and tissue parasites in the wall of the mosquito's midgut.

In general, however, the protozoan parasites repeat conditions already described for Metazoa. One finds the degeneration of organs superfluous under conditions of parasitic existence, the formation of organs of attachment, such as hooks, suckers, etc., the noteworthy fecundity already commented upon for metazoan parasites; and finally the alternation of generations and of hosts is a common feature among the Protozoa also.

An encysted condition of the entire individual or of a group of spores aids in the dispersal of the species, which are all inhabitants of a moist environment and cease activity at once on withdrawal of the water. This general habit renders it difficult to distinguish between mere commensals which find in the alimentary canal of higher forms conditions for their ordinary slime-inhabiting existence without exerting any influence upon the host, and such as are parasites in the true sense.

A true parasite draws its nourishment from the host and affects it at least to that extent. When this takes place, as with protozoan parasites largely, within a tissue or even a cell, morbid conditions are evoked, even though they remain local in some cases. That functional disturbances result is evinced by the relatively large number of protozoan diseases among animals and plants. These sometimes take the form of tissue proliferations, as has been clearly demonstrated for plants. An effort to trace similar effects in animals is found in the extensive literature on cancer parasites. Thus far, however, no sufficient evidence has been brought to establish the parasitic nature of such abnormal growths, and none of the supposed "parasites" can be clearly recognized as Protozoa. It should be noted in passing that in addition to the mechanical effect of cell parasites a chemical influence of at least equal importance is exercised by the excretions of the organism, the metabolic products set free in the protoplasm of the host cell. In some cases this is a factor of great importance, as also in the case of bacterial diseases; its significance among Protozoa is not yet sufficiently investigated.

It is noteworthy that in many instances a protozoan infection is self-terminating, either that a type of immunity is acquired by the host, or that the reproductive cycle of the parasite reaches its limit without a change of host or alternation of generations. MacNeal and Novy have recently endeavored to determine experimentally the possibility of securing attenuated cultures of one protozoan parasite (*Trypanosoma*) with absolutely negative results; the last generation from a culture more than a year old was even more virulent than the organism at the start.

Regarding means of infection but little definite evidence is at hand. It is inferred that encysted forms furnish the ordinary means for transferring the species to a new host, and yet in many cases experiments along this line have been without results. In other cases it is now known that the transfer takes place through some biting insect, which in some cases, if not all, acts as the host for another phase in the life history of the parasite, and is capable of transmitting the disease only after a period sufficient to allow of the development within its body of the specified portion of the life cycle.

In those cases in which the life history has been worked out, means of preventing the infection of the human host constitute the evident limitation to the spread of the disease caused by the parasite. The inauguration of a simple but effective prophylaxis for malaria and yellow fever ranks rightly as among the most brilliant achievements of scientific medicine. In cases in which the life history of the parasite is unknown, the prophylaxis is necessarily vague and uncertain. It is wise to emphasize here the importance of co-operative effort on the part of trained observers, both in medicine and in zoology, to elucidate fully the problems which necessarily offer almost insuperable obstacles to the investigator approaching them from the single standpoint.

All the varied modifications within the branch of Protozoa may be grouped into four well-defined classes which are now almost universally recognized. These may be briefly outlined together with their major subdivisions, following in the main the classifications of Bütschli, Calkins, and Doflein, and noting principally those groups which contain forms found in the human body.

Class I. Sarcodina.—Naked or shelled Protozoa, characterized in the free adult condition by the formation of changeable processes of protoplasm as organs of locomotion. These pseudopodia may be lobose, digitate, reticulate, or finely radiate, and may be formed over the entire surface of the body, or only at definite points. Reproduction takes place by simple division and by spore formation.

Subclass 1. Rhizopoda. Naked or shelled Sarcodina, having lobose or reticulate pseudopodia. The young may be flagellate as well as amœboid, and are produced by multiple division of the active cell or during encystment. Included among Amœbina are naked forms (Gymnamœbina) with both free and parasitic species, and also shelled forms (Thecamœbina) only free living.

Subclass 2. Heliozoa. Naked or shelled Sarcodina, typically spherical, with little change of form by amœboid movements. Pseudopodia fine, filiform, radiating from all parts, provided with axial filament and rarely changeable, exclusively free living forms.

Subclass 3. Radiolaria. Marine Sarcodina with pseudopodia like those of Heliozoa, but always provided with internal chitinous capsule which encloses the nuclei. Skeleton of acanthin or silica sometimes absent. A very large group of free living forms.

Subclass 4. Mycetozoa. Terrestrial saprophytic or parasitic forms, also known as Myxomycetes or slime moulds, and included under the fungi by some botanists. The motile amœboid or flagellate swarm spores, the plasmodia or colonies formed by the fusion of numerous amœboid individuals, and the holozoic mode of nutrition are characteristically animal features. On the other hand, the production of spores in sporangia, often provided with stalks and other plant-like structures, are taken to prove the plant nature of these forms. All known parasitic forms in this group attack plants.

Class II. Mastigophora.—Protozoa of variable form, naked or with cell membrane; they move by flagella, which vary in number from one to eight on each cell.* Mouth, contractile vacuole, and definitely formed nucleus usually present. Small forms with tendency to formation of colonies.

Subclass 1. Flagellata. Small organisms with one or more flagella at anterior end, usually actively motile, but capable of encystment. Reproduction by longitudinal fission of free form or by multiple division in encysted stage. Rarely transverse fission occurs.

Subclass 2. Dinoflagellata. Naked or shelled forms with two flagella, one of which extends out from the body, while the other is wrapped around the animal. No parasitic forms.

---

* *Multicilia lacustris* Cienkowsky has many flagella, distributed over the whole body.

Subclass 3. Cystoflagellata. Large marine forms with parenchymatous protoplasm and firm membrane; marine; no parasitic forms.

Class. III. Sporozoa.—Exclusively parasitic forms, in the adult condition without flagella or cilia, contractile vacuole, and opening for ingestion of solid food. Reproduction always by spore formation, usually within a firm membrane. Alternation of generations only exceptionally wanting. The young forms regularly begin the life cycle as cell parasites; other stages may be the same, or tissue or organ parasites.

Subclass I. Telosporidia.—At the end of a vegetative period the entire cell divides into sporocysts.

Order 1. Gregarinida. Vegetative stage intracellular at first, full-grown organism extracellular; fertilization isogamous, fertilized forms permanently extracellular. A large group of forms parasitic in alimentary and body cavities of invertebrates.

Order 2. Coccidiomorpha. Vegetative stage permanently intracellular; fertilization anisogamous; sexual generation permanently or temporarily intracellular. Many of the most important protozoan parasites of man fall in the limits of this group.

Subclass 2. Neosporidia.—Sporocysts are produced continually and at the expense of only part of the cell. In general these forms are not well known.

Order 1. Cnidosporidia. The spores possess one or more polar capsules which contain a coiled thread like a nematocyst. The sub-orders are: (1) Myxosporidia, parasitic in water-inhabiting vertebrates; and (2) microsporidia in certain invertebrates also. Both are not important here.

Order 2. Sarcosporidia. Parasitic in muscle cells of terrestrial vertebrates, probably without polar capsule. Little known, but important.

Class IV. Infusoria.—Protozoa with motor organs in the form of cilia, whether simple or united into membranes, membranellæ, or cirri; with macro- and micronucleus; reproduction by division and by budding, combined with an exchange of nuclear matter known as conjugation.

Subclass 1. Ciliata. Cilia persistent except when encysted. Cytostome usually present. Mostly free forms; some parasites of man and other animals.

Subclass 2. Suctoria. Cilia only on young swarming stage. Food taken in by special sucking tubes; no cytostome. No human parasites.

According to this classification the forms which have been reported from man may be arranged as given in the following list, in which, however, chiefly those species are included which are definitely accepted. Some few doubtful forms of special significance are listed here; and still others are referred to in the text under general headings.

Class Sarcodina.
  Subclass Rhizopoda.
    Order Amœbina.
      Suborder Gymnamœbina.
        Entamœba coli.
        Entamœba histolytica.
        Amœba Miurai.
        Leydenia gemmipara.
Class Mastigophora.
  Subclass Flagellata.
    Order Protomonadina.
      Cercomonas hominis.
      Monas pyophila.
      Trypanosoma gambiense.
      Cystomonas urinaria.
  Order Polymastigina.
      Trichomonas vaginalis.
      Trichomonas intestinalis.
      Lamblia duodenalis.
Class Sporozoa.
  Subclass Telosporidia.
    Order Coccidiomorpha.
      Suborder Coccidia.
        Eimeria Stiedæ.
        Eimeria hominis.
        Eimeria bigemina.
      Suborder Hæmosporidia.
        Plasmodium malariæ.
        Plasmodium vivax.
        Plasmodium immaculatum.
  Subclass Neosporidia.
    Order Sarcosporidia.
      Sarcocystis Lindemanni.
Class Infusoria.
  Subclass Ciliata.
    Order Holotricha.
      Chilodon dentatus.
    Order Heterotricha.
      Nyctotherus faba.
      Balantidium coli.
      Balantidium minutum.

The relation of the Protozoa to disease is only just beginning to be investigated. At every point the student is met by the gross insufficiency of present knowledge; a host of isolated observations is on record. Some are clearly wrong, while others are indicative of important discoveries, though the presence of certain organisms during specific diseases needs confirmation, and equally their relation to the inception and progress of the malady. New methods must be worked out for the culture no less than the study of these forms, and the same sort of rigorous analysis is demanded in demonstrating their relation to disease which has been given to bacteria. It seems altogether probable that they will play a prominent rôle in medical investigation in the near future, but in the present state of our knowledge any review of the group must necessarily be only a tentative one.

The class of Sarcodina, or sarcode animals, is typically represented by the common free-living amœba, which has its parallel in the white blood cells. The most characteristic structural feature is the ability to protrude a portion of the body substance in the form of a process or pseudopodium by which locomotion is achieved, and also the food particles are seized and engulfed. The subdivision of the class rests primarily upon the precise character of the pseudopodia.

Under the order Amœbina are included such forms as possess lobose pseudopodia, and the sub-order of Gymnamœbina embraces such of these as are without a shell. All the human parasites which fall within the Sarcodina are included in a few closely related genera of this sub-order. While the structure is simple, and in agreement with that of the simple free-living forms of the group, it is impossible to demonstrate that this is not the result of degeneration from more highly differentiated forms by virtue of the parasitic mode of existence. The parasitic species are most probably to be traced back to slime-inhabiting, free-living forms, a transition from which to the present parasitic existence seems most immediate and simple in physiological adjustment.

The ordinary method of reproduction is by simple division, recurring at frequent intervals and conserving the rapid multiplication of the species. This form has long been known, and is to be observed frequently in all truly independent organisms of this type. Recent investigations have disclosed another reproductive type: under definite circumstances, possibly only after fusion of individuals or some exchange of nuclear matter, the amœba forms a cyst within which the nucleus undergoes multiple division, and ultimately the protoplasm arranges itself about the new nuclei, so as to give rise to an equal number of small amœbæ. When these desert the cyst there is left behind a residual mass of protoplasm. At first distinguishable slightly in structure as well as size, the small amœbæ thus produced soon grow to the size and appearance of the adult. The occurrence of this stage in the life cycle has not yet been demonstrated for parasitic amœbæ, except very recently for *Entamœba coli* and *E. histolytica;* but if present it may well be related to the spread of the species as found in the change of hosts. The necessity for such a stage would explain the ineffectual attempts which have been made to inoculate new hosts by direct transference of the ordinary parasitic form.

In the genus *Amœba* the separation of species is exceedingly difficult on account of the insignificant features available for purposes of differentiation. There are those who lump the forms found in man with such as occur in other mammals under a single species, and there are also those who contend that each host shelters a distinct parasitic species, and bring as evidence the individuality of parasitism in other groups. But on the other hand it may be urged that the amœbæ are not highly differentiated as parasites, and mere difference in host animal has long since been abandoned as a distinguishing mark between parasites from higher classes. It is certain that no positive statement can be made until more complete information is obtained regarding the life cycle of the species. At present no one can affirm that a given species does not possess a free-living generation as well, or even that it is not a normal free-living form which under favorable circumstances has taken up the parasitic mode of life; in which case it should be regarded as a mere accidental parasite. Furthermore of only one human parasite included within this group can it be said positively that it is more than a harmless commensal. Although facts have been adduced to show that others also play a pathogenic rôle, the question must still be regarded as at least an open one.

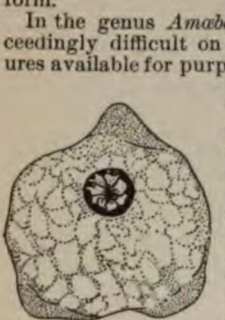

FIG. 5163. — "*Amœba coli*," Stained Preparation. Magnified. (After Doflein.)*

Among the amœboid bodies which one finds in nature and in cultures many are only developmental stages rather than independent organisms, and the same may well be true of some of the parasitic forms. On the other hand, the distinction between such organisms and various structural elements of the human body is often a very difficult task, and some of the purported parasitic species are in fact referable to the misinterpretation of the body cells referred to above.

In the new genus *Entamœba* are included two important human parasites, the life history of which has recently been well elucidated. The other imperfectly known species are left in the old collective genus *Amœba*, but fuller knowledge may result in the transfer of some or all to this same or other new genera according to the facts ascertained regarding the life history of the individual forms.

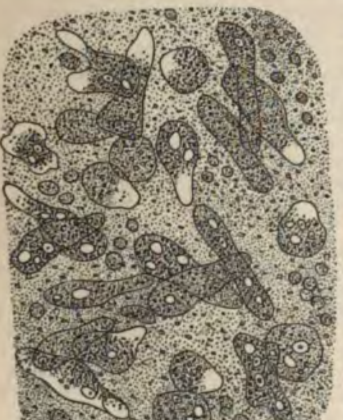

FIG. 5164.—"*Amœba coli*," in Intestinal Mucus. Magnified. (From Braun, after Lösch.)*

Entamœba coli (Lösch 1875).—(Syn.: *Amœba coli* Lösch 1875; [?] *Amœba dysenteriæ* Councilman and Lafleur 1891; *Entamœba hominis* Casagrandi e Barbagallo 1897; *Entamœba coli* Schaudinn 1903.)

Form oval or pyriform (Fig. 5163); diameter from 0.0075 to 0.05 mm.; nucleus distinct in life, spherical, 0.002, usually 0.003–0.007 mm. in diameter, with heavy nuclear membrane and many small nucleoli. Ectosarc not distinct save in pseudopodia, where it is conspicuous, everywhere less refractive than endoplasm. Pseudopodia rare, usually one or two, broadly lobed and heavy (Fig. 5164). Endosarc finely granular, with one or several non-contractile vacuoles, and many objects ingested as food; such are leucocytes, erythrocytes, eosinophilia, bacteria, starch granules, fæcal particles, epithelial cells, etc. (Fig. 5165). The digestion of erythrocytes is accomplished without excretion of any pigment masses.

Reproduction in the human intestine by simple division and by schizogony, with the formation normally of eight daughter cells. In fission the nucleus undergoes amitotic division, while in schizogony complicated nuclear changes are seen with the elimination of a portion of the chromatic substance. As a preliminary step to encystment all foreign bodies are extruded from the protoplasm, which thus becomes clear and transparent. These cysts, first discovered by Grassi, were carefully studied by Casagrandi and Barbagallo. They constitute the means of transmitting infection, as has been determined experimentally, first by Calandruccio who swallowed such encysted forms and found the developed amœbæ twelve days later in the fæces. The normal seat of this species is the upper region of the colon, and the vegetative forms appear in the fæces only when the latter are semi-fluid by reason of disease or of the administration of medicaments. The cysts which are so characteristic as to be confused with nothing in the fæces are capable of further development only when they contain eight nuclei. Other cysts have been determined experimentally by Schaudinn to be incapable of development, even though they actually constitute the major part (eighty per cent.) of those evacuated. In old dry fæcal matter only the forms with eight nuclei are present, and in the colon of the next host eight small amœbæ are formed by division of the protoplasm and emerge to begin a new infection and a new vegetative period.

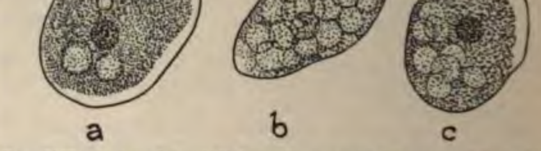

FIG. 5165.—"*Amœba coli*," from Dysenteric Intestine, more or less filled with Erythrocytes: Nucleus also visible. Magnified. (From Doflein after Roemer.)*

This species occurred in East Prussia in fifty per cent. of the cases examined; in Berlin the number found infected was 1:5, and on the Adriatic coast 2:3. The exact distribution of this species has not been further worked out, though the numerous reports lead one to believe that it is a cosmopolitan species.

Grassi was the first to identify the species from the normal human canal, and Schuberg confirmed this by a considerable series of cases. Casagrandi and Barbagallo demonstrated conclusively that it does not possess pathological characteristics, and quite recently Schaudinn in an exceedingly extensive and careful investigation showed the existence of two very similar species, hitherto generally confused, one of which, that under consideration, is a harmless commensal, and the other to be considered next a dangerous parasite. The first lives in the human host in health and is widely distributed; it multiplies excessively in various intestinal disturbances, and is brought to the exterior in fæcal matter by any conditions which produce fluid or semifluid discharges from the canal. It can indeed coexist with the following species, which is pathological in the extreme. The present

---

* In advance of the appearance of Schaudinn's figures it did not seem advisable to do more than quote the name given in the original from which these cuts were taken.

* In advance of the appearance of Schaudinn's figures it did not seem advisable to do more than quote the name given in the original from which these cuts were taken.

species was first carefully studied by Casagrandi and Barbagallo, and is easily recognized from their account. In the majority of cases reported, however, it is difficult to say which form was under examination, although it is probable that in many of them both species were studied and the description contains features characteristic of both. This is the case with the full and valuable account given in Vol. I. of the HANDBOOK. (See *Amœba coli.*) To this admirable review of the subject have been added here only such features as aid in distinguishing the two recently differentiated species.

Entamœba histolytica Schaudinn 1903. (Syn.: [?] *Amœba dysenteriæ* Councilman and Lafleur 1891.)

In many general features like *E. coli*, often occurring together with the latter, and heretofore generally confused with it, yet distinguishable by the following features: Ectoplasm well developed and present as distinct plasma zone, more highly refractive than the endoplasm, viscous in consistence and glass-like in appearance. Nucleus rarely visible in life, almost homogeneous; little refractive, poor in chromatin, usually with a single nucleolus in centre, and with very delicate nuclear membrane, if indeed any is present. Reproduction by division and budding, the latter often multiple, and both following amitotic nuclear division. Cysts with eight daughter cells never found. Resting stages are formed when the fæces grow firmer; the progress of their formation begins by the rejection of chromatin from the nucleus until the entire plasma is filled with chromatin masses, and the nucleus itself degenerates and is absorbed or thrown out. The chromatin masses collect in the peripheral zone of the plasma and come to lie in ectoplasmic hillocks, which develop to free spherules on the surface of the cell. These structures measure only 0.003–0.007 mm. in diameter, and soon acquire a yellowish-brown membrane and a highly refractive semi-opaque appearance. The remainder of the amœba goes to pieces. Schaudinn was able experimentally to evoke a severe dysentery by feeding these spores to cats, and maintains on good grounds that such spores constitute the only means of producing a new infection normally. Injections per anum of the vegetative form alone produced a typical case of the disease, as Jürgens showed first.

While *E. coli* has no power to penetrate the healthy epithelium, *E. histolytica* is able to enter anywhere and force its way through. In this process the amœbæ push the cells apart, and even force them free from the layer. These features were first correctly described by Jürgens, who gave a full and accurate account of this species. His discoveries on the cat have been confirmed by the observations of Schaudinn on man also. The amœbæ were found in sound regions of the mucosa in the glands of Lieberkühn, could be followed on into the submucosa. Undermining of the mucosa and abscess formation follows in later stages of the malady. These investigations demonstrate clearly that *E. histolytica* is a true tissue parasite, like the Myxosporidia, and indeed the most dangerous of all Protozoa yet known, and that it is the cause of ulcerous amœbic enteritis.

Jürgens is the only author who in the opinion of Schaudinn has characterized this species in recognizable form, although the species was probably before many authors, who were unable to differentiate it clearly from the other species, *E. coli*, with which it was certainly associated in some cases reported.

The material from which the pathological species was obtained by Schaudinn came from a limited number of cases of tropical dysentery acquired in Egypt, China, and Siam. The real geographical distribution of the species is thus evidently but imperfectly known.

It is difficult to pass satisfactorily upon the specific character of the forms hitherto observed in the United States, and only two references will be made. The observations of Craig (*Medical News*, March 16th, 1901) seem to have been made on *Entamœba coli* of Schaudinn, in which the former described as "oval spots" the formation of the encysted daughter cells already well known from the work of Casagrandi e Barbagallo. The splendid monograph of Councilman and Lafleur in my opinion deals unmistakably with *E. histolytica* of Schaudinn. The description of the amœbæ is very detailed and precise, and apparently agrees minutely with the characters, such as the form, appearance, and position of the nucleus, advanced by Schaudinn to separate the pathogenic *E. histolytica* from the harmless *E. coli*. The absence of any reference by such careful observers to the formation of cysts, which is easily observed in *E. coli*, must be regarded as confirmative evidence of the presence of the other species. If this opinion with regard to the identity of the forms proves to be correct, the specific name given by Councilman and Lafleur will have to be used in preference to the later form given by Schaudinn and the species will be known as *E. dysenteriæ* (Councilman and Lafleur 1891). Although illustrated by very inadequate figures, the pathological lesions caused by this species are described by these authors with great fulness and care, and anticipate very largely the work of Jürgens, to which Schaudinn accords such well-merited praise.

The following forms included under the generic name *Amœba* are classified thus rather tentatively, as our knowledge of the life history at least is too limited to allow of greater precision. Probably some at least are related to the species just described if not identical with them.

Amœba Miurai Ijima 1898.—Normally isolated individuals (Fig. 5166), adhering in conglomerate-like clusters only when dead or dying. Living specimens, spherical or ellipsoidal, having at one pole a small rounded protuberance or villous knob, which is closely set with fine pseudopodia. Diameter 0.015–0.038 mm. Villous knob papilliform or hemispherical, 0.01 mm. in diameter at base, but capable of entire retraction at times, or the fine pseudopodia may be entirely withdrawn. Nucleus round, oval, or reniform, 0.008–0.015 mm. in diameter, two or three being found in the single cell as often as one. Ectoplasm visible only in villous knob; endoplasm finely granular with one to several conspicuous non-contractile vacuoles and minute oil-like corpuscles.

This form was found by Miura and described by Ijima. It occurred in the serous fluid accumulation of peritoneal and pleural cavities in a female, twenty-six years old, who died from peritonitis and pleuritis endotheliomatosa. The amœbæ were absent at first from the fæces, but made their appearance two days before the patient's death, concomitantly with hemorrhage in the intestine. Living and dead individuals were found together in the freshest serous fluid under rigid precautions against injurious influences, and this is regarded by Ijima as evidence of the abnormal occurrence of the parasite. It has not been reported since then, and is explained by some authors on the basis that the supposed amœbæ were only "exudate cells." Lühe states that this is unquestionably the case.

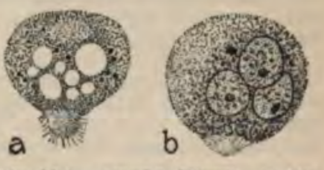

FIG. 5166.—*Amœba Miurai.* *a*, Living; *b*, from specimen preserved in acetic acid. × 500. (After Ijima.)

A considerable number of so-called amœbæ have been reported from various organs in man, and usually pathogenic characteristics have been attributed to them. They are known mostly from single records of their occurrence, and often lack both name and recognizable description. It has been suggested that they are commensals, and of secondary importance. It is equally probable that some at least are occasional or accidental parasites, and devoid of general importance in human pathology. Owing to the general uniformity of structure in this group all but the most careful descriptions are worthless for future study and comparison with other species. A few of the best accounts of these uncertain forms are noted here for reference.

Amœba Kartulisi Doflein 1901.—Diameter 0.03–0.038

mm. without distinct ectosarc and endosarc. Plasma coarsely granular, with very small nucleus (or nucleolus?), demonstrable only by staining. Movement more rapid than in *Entamœba coli*. Usually only one or a few pseudopodia, long, digitate and rapid in formation. Reproduction not observed.

This species was found by Kartulis in Alexandria, where it occurred in an Arabian, in a tumor the size of an orange, on the right mandible. In the thick pus and on fragments of extracted bone the amœbæ occurred together with numerous bacteria. They had been feeding on blood and pus corpuscles. Although apparently distinct from *Entamœba coli*, Doflein inclines to regard their connection as not impossible, and views as even more probable this interpretation of the amœbæ from an abscess in the oral cavity reported by Flexner. These were described as larger than leucocytes, with granular vacuolated plasma and a nucleus demonstrable only with some uncertainty. Although in both these cases the presence of *Entamœba coli* in the host had not been shown by any antecedent dysentery or fæcal examination, it has already been stated that this species may be present in the normal intestine, and its occurrence outside the canal in abscesses is abundantly demonstrated by other cases. It is less probable this form may have been *Entamœba histolytica*, though the description is not distinctive, as the absence of lesions in the canal can hardly be explained if the pathogenic species was present.

Amœba urogenitalis Baelz 1883.—Diameter 0.022–0.05 mm. Plasma coarsely granular, containing one or several nuclei, excretory products, and erythrocytes. Movement slow, by formation of short pseudopodia. Encysted forms possibly occur.

Originally found in numbers in the bloody urine and vaginal mucus of a Japanese female, twenty-three years old, who shortly before her demise from tuberculosis manifested hæmaturia with strong cystic tenesmus. (*Cf.* Vol. I., p. 233, HANDBOOK.) Similar cases have been reported by many authors. In Jürgens' case chronic cystitis was associated with small mucous cyst filled with amœbæ; these were also present in the entire vagina. The descriptions are scanty and do not render a differentiation between these forms and *Entamœba coli* and *E. histolytica*, either structurally or clinically easy at present. Pathogenic characteristics are certainly not distinctly shown, and in so far this case belongs more probably to *E. coli* if to either. Better knowledge of the species and more careful examination of the reports of previous observers may make it possible to refer some such cases to a definite species; but many will always remain uncertain.

Amœba buccalis Sternberg 1862; *Amœba dentalis* Grassi 1879; *Amœba gingivalis* Grassi 1849.—All these species were discovered in tartar scraped from the surface of human teeth. They have not been reported a second time, and Celli and Fiocca state specifically that they have failed to find amœboid organisms in the oral cavity. Grassi himself suggested the possibility of confusion with salivary corpuscles.

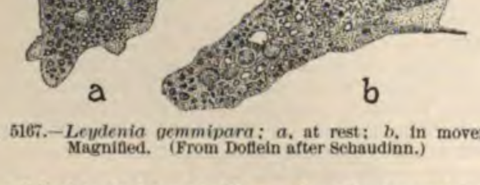

FIG. 5167.—*Leydenia gemmipara*; *a*, at rest; *b*, in movement. Magnified. (From Doflein after Schaudinn.)

Amœba pulmonalis Artault 1898.—In an examination of the contents of a large pulmonary cavity a small number of amœbæ were found among the leucocytes, which were distinguishable by firm contour, much finer and more uniform granulation, and a distinct nucleus or vacuole. In appearance like the epithelial cells found in sputum they manifested changes in form and position through the slow formation of pseudopodia. They were also more highly refractive, and resisted methylene blue or fuchsin longer than leucocytes, but when preserved they stained readily and were indistinguishable from the latter. Despite the conjectures of the discoverer their real nature remains entirely unknown.

Leydenia gemmipara Schaudinn 1896.—Irregularly spherical or polygonal in form when resting (Fig. 5167, *a*), surface with prominent verrucosities. Ectosarc and endosarc not distinctly limited, but pseudopodia more hyaline than the opaque body with numerous highly refractive yellowish granules. Diameter of body, 0.003–0.036 mm. Nucleus single, spherical, distinct in life, and in the preserved specimen regularly one-fifth the diameter of the body; movement very slow, produced by formation of a broad, hyaline lamella at the anterior margin; streams of granular endosarc extend to the margin of this lamella (Fig. 5167, *b*), and may even project beyond it as pointed pseudopodia. The endoplasm contains granules, crystalline bodies, interpreted as excretory, and numerous vacuoles which increase in size toward the centre. A pulsating vacuole is present and contracts at intervals of about fifteen minutes.

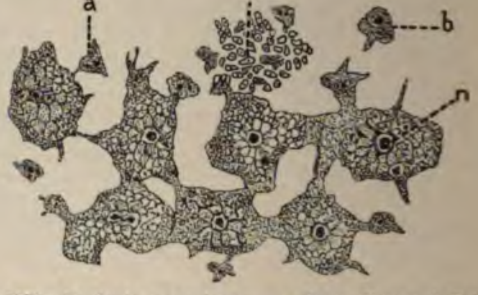

FIG. 5168.—*Leydenia gemmipara*. *a*, *b*, *c*, Young individuals formed by gemmation. *n*, nucleus. Magnified. (From Doflein after Schaudinn.)

Two or more individuals frequently unite without fusion of the nuclei, and plasmodia are formed by the union of many single individuals. Both division and gemmation occur. In the former the size of the resulting amœbæ may be very different, but is always proportional to the size of the nuclei (5 : 1). The nucleus divides directly, and the bud which originates as a protuberance from the surface of the amœba gradually works free and becomes an independent individual, which may at once undergo multiple division, giving rise to a mass of small spore-like forms (Fig. 5168).

Many years ago Lieberkühn observed in ascites fluid associated with malignant tumors peculiar cells; and similar structures were seen later by others. In 1896 Leyden and Schaudinn, on the basis of an exact investigation of these bodies in a particular case, determined them as a new parasitic rhizopod. Leyden had found them in the ascitic fluid of two patients in whom positive evidence of gastric carcinoma and of tumors in the peritoneal cavity was furnished. The amœbæ appeared in numbers in fluid drawn off from the cavity, and could be kept alive in fluid preserved several days under aseptic conditions. Schaudinn studied the amœbæ carefully and pronounced them to be unmistakably parasitic forms. Some later critics have inclined to reject this view, and regard them as descendants of the human tissue cells or pathologic neoplasms. L. Pfeiffer especially has maintained that similar large amœboid cells ("exudate cells") occur in variola, vaccinia, varicella, herpes zoster, etc., and yet the contractile vacuole, peculiar nuclear structure, and reproductive processes of *Leydenia* indicate unmistakably an independent organism, as well as many other features in which it resembles various related free-living forms.

Originally Leyden and Schaudinn were inclined to connect this form with carcinoma, but expressed no positive opinion on this point. Unfortunately it has not been studied by subsequent investigators, and in fact has been found but twice since then, although often sought for under similar circumstances. Recently Schaudinn has advanced the view that this form is probably an accidental commensal.

The class of the Mastigophora includes a great variety of organisms, having in common hardly more than the possession of vibratile organs of locomotion known as flagella, which by greater length, lesser number, and type of movement are easily distinguishable from cilia. The group shows relationships in many directions, and affords an almost unbroken line of transition to forms which are typically plant organisms. Here, again, as in the last class (Sarcodina) the uniformity of structure, coupled with an even smaller average size and very insufficient acquaintance with the life history, render it difficult to speak positively regarding many of the organisms. Of the sub-classes, which are founded upon the number and arrangement of the flagella, the character of the cell body and general habits of life, only one, Flagellata, is of importance here, as the others contain no parasitic forms.

The general form of the body, the number and position of flagella, and the precise method of reproduction serve to distinguish in the sub-class Flagellata five orders. Only two of these embrace human parasites and demand consideration here, namely: Protomonadina and Polymastigina.

The Protomonadina are small forms, often tending to form colonies. They have at the anterior end one flagellum, two similar flagella, or two or three dissimilar flagella. In many parasitic species an undulating membrane accompanies a single flagellum. Doflein gives the following key for the determination of those families which include parasitic species:

1. A single flagellum on anterior end 2
   Two flagella on anterior end.............Bodonidæ
2. An undulating membrane along the side of the body ....Trypanosomidæ
   No undulating membrane present..Cercomonadidæ

Cercomonas.—The species in this genus are rather uncertain. Many forms have been assigned to it which later studies have shown to belong to other genera. Confusion is possible both with plant organisms and with mere developmental stages of other groups. The species are small and colorless; in form round or oval, with a very large flagellum, which is projected ahead in locomotion. Many of the forms reported from the human body and assigned to this group are imperfectly known, often found but a single time, and in many cases probably pseudoparasites of various degrees. One or two of the more distinct forms need brief mention here.

Cercomonas hominis Davaine 1854.—Body pyriform, pointed posteriorly, with single flagellum at anterior end. Length 0.01–0.012 mm. Movement rapid, capable of attaching themselves by posterior tip. Smaller variety 0.008 mm. long.

Found in the dejecta of a cholera patient, the smaller variety in typhoid dejecta. Various later reports may be assigned to this species, including that of Lambl in 1875, which has often been erroneously identified as the same as the species described under the same name by this author in 1859. The latter will be discussed under its present name of *Lamblia duodenalis*. Some authors have assigned the former species to *Trichomonas*, forgetful of the fact that it possesses but a single flagellum.

It would be hazardous to assert that all typical cercomonads thus far described from the human host fall unquestionably into the limits of a single species; yet in the absence of contradictory evidence they may for practical purposes be considered as such. These forms have been found in the alimentary canal, the bronchial system, in pleural exudate, and in an *Echinococcus* cyst. Encysted forms have also been described. All investigators have not been equally careful to demonstrate the intestinal origin of such forms as were found in fæces, and which may have been due to secondary contamination of the fæcal material. Among numerous records only those of Councilman and Lafleur and of Dock concerning the occurrence of such forms in this country need be mentioned.

Monas pyophila R. Blanchard 1895. (Syn.: *M. pyophyla* Neveu-Lemaire 1902.) Form similar to large spermatozoa, 0.03–0.06 mm. in diameter of body, with long filament from rounded pole, resembling a flagellum, yet capable of retraction when the form becomes nearly spherical. Outside a cuticular (?) layer, which extends through the body in partitions, dividing it into three regions. Movement rapid, accompanied by change of form.

Found by Grimm in sputum and pus of abscesses in lung and liver of patient in Japan.

The Trypanosomidæ are parasitic forms with a chief flagellum directed anteriad, usually two-edged, with more or less of a spiral twist in the body, and with one edge of the body provided with an undulating membrane. The numerous species are hæmatozoa in vertebrates, though some live in the body cavity and alimentary canal of both vertebrates and invertebrates. Those forms of importance here all fall in the genus *Trypanosoma* s. str. Much difference of opinion prevails as to the number of species and their limits. Most of them are very poorly known, although several so-called species were discovered as much as sixty years ago; indeed of no form is even an approximately complete account of the life history at hand. Various species are recognized in various parts of the world as the cause of specific diseases among domesticated animals, which have assumed economic importance of the first rank. The most prominent of these are the following, together with the range and host of each species listed.

Trypanosoma Lewisi, in rats and (?) the hamster, reported from Europe, Asia, Africa, and North America, and causing at times fatal epidemics.

Trypanosoma Brucei, in cattle, horses, mules, and wild animals, gives rise to the *nagaña* or Tsetse-fly disease in Africa south of the Sahara.

Trypanosoma equiperdum, in horse, ass, and other domesticated species by inoculation, causes *dourine* in the circum-Mediterranean region.

Trypanosoma Evansi, in mammals, especially domestic, where it causes the *surra* in India, China, Burmah, and the Philippines.

Trypanosoma equinum, in horses, causing *mal de caderas* in South America.

Trypanosoma Theileri, in cattle, producing the *galziektè* in South Africa.

Although but little evidence is at hand, the weight of opinion is against any possibility of the transmission of these species to man.

Some structural features of the genus *Trypanosoma* s. str. need brief mention. The lancet-shaped body (Fig. 5169, *a*) shows a finely granular endoplasm and a distinct though very delicate hyaline ectoplasmic layer. The single flagellum arises near the posterior end in connection with the highly refractile granule variously denom-

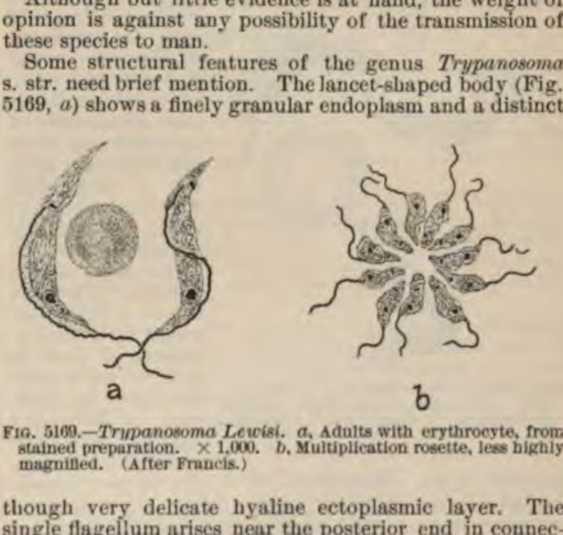

FIG. 5169.—*Trypanosoma Lewisi.* *a*, Adults with erythrocyte, from stained preparation. × 1,000. *b*, Multiplication rosette, less highly magnified. (After Francis.)

inated centrosome, micronucleus, and nucleolus. The flagellum continues along the body as the thickened outer margin of the undulating membrane, and projects free from the anterior end of the animal. The prominent nucleus occupies a slightly different position in different species; it is rich in chromatin and stains deeply in prepared specimens.

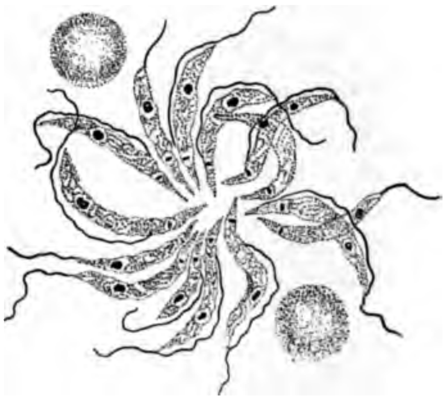

FIG. 5170.—*Trypanosoma Lewisi.* Auto-agglutination. Highly magnified. (After Francis.)

Three types of reproduction are imperfectly known: a typical longitudinal division, a budding said by Senn to be more common, and a segmentation or multiple division into numerous spores (?) arranged in rosettes (Fig. 5169, *b*). The rosette formation is regarded by some authors as the result merely of the successive division of an ordinary individual of the species. These rosettes of enormous size, embracing several thousands of individuals, occur characteristically in cultures of *Trypanosoma Lewisi* (Fig. 5170). Such cultures have been recently successfully obtained by McNeal and Novy in a strictly pure form, and have been maintained for somewhat over a year. The great importance of this step for the study of the pathogenic activity of the organism and of the possible protective measures in combating the disease is evident at once. The species found in man is

Trypanosoma gambiense Dutton, 1902. (Syn.: *T. hominis* 1903; *T. Nepveu* Sambon 1903.) Length in stained preparation (Fig. 5171), including flagellum 0.018–0.025 mm., width 0.002–0.0028 mm. Free part of flagellum about one-third of total length. Anterior end attenuated along flagellum, posterior end roughly conical, very blunt. Oval macronculeus just anterior to centre of body, occupying entire width of animal. Near posterior end dark spot, the micronucleus (the centrosome of Laveran and Mesnil), and just anterior to it a large vacuole well marked. The flagellum ends at the upper edge of this vacuole. The first record of the occurrence of a trypanosome in man is said to have been published by Nepveu in 1891, and again in 1898. The description given, however, is too scanty to admit of any opinion regarding its general character, though many are inclined to interpret it as a member of the genus *Trypanosoma.* This species was discovered in 1901 by Dutton in the blood of an Englishman in government employ on the Gambia River. The case was under observation some time, namely, until the patient died in January, 1903, and manifested the following clinical features: general weakness, irregular lapsing fever lasting one to four days with apyrexial periods of two to five days, some œdema, injection of the skin, enlargement of the spleen, constant frequent pulse, and hurried breathing. These symptoms were associated with no definite organic lesions.

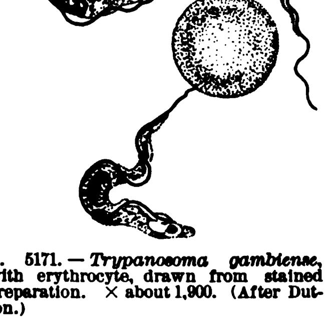

FIG. 5171.—*Trypanosoma gambiense,* with erythrocyte, drawn from stained preparation. × about 1,900. (After Dutton.)

In many prepared slides and fresh blood mounts there were found no malarial organisms. The number of trypanosomes present varied from one to fifteen, but in apyrexial periods none were detected in the blood. The parasite usually progressed with the flagellum in front, but occasionally reversed direction for a short distance. In slow progression wave-like motions start in the flagellum and are communicated to the undulating membrane; in rapid motion the body rotates on its longitudinal axis so that the undulating membrane appears as if spirally arranged. In one instance a mononuclear leucocyte was observed which had partially engulfed a trypanosome, only the flagellum and a small part of the anterior end of the body remaining free.

In films of blood taken from a child three years old the parasite was discovered again and associated with it malarial organisms. Annett points out that the chronic character of the disease, the rarity of the parasites, their apparent absence at long periods from the peripheral circulation, and the occasional rise in temperature favor confusion with malaria in diagnosis.

Later further cases of the malady have been identified by Dutton, Manson, and others, making in all six cases on the Congo River and seven on the Gambia, which are nearly equally divided between natives and Europeans. It is thus evidently not rare in tropical Africa, as Dutton found his seven cases in somewhat more than one thousand examinations in Senegambia. Two investigators seem to have identified it in India also, and it may be expected to occur in other countries as well, as do the corresponding affections of domestic animals.

A final most recent contribution of great importance to this subject has been made by Castellani, who found *Trypanosoma* in the cerebro-spinal fluid of natives afflicted with the so-called "sleeping sickness." This hitherto entirely unexplained disease, epidemic in certain regions of Africa, attacks only natives, and is characterized by a drowsy condition culminating in deep coma, with an all but universally lethal outcome in from three to twelve months. Hyperæmia of the arachnoid vessels is the only known pathological feature. Bacteriological investigations have remained without result, and the theory of Manson that the cause of the malady lay in the presence of *Filaria perstans* has already been referred to in another article (*Nematoda*). Castellani's hypothesis has been greatly strengthened by the communication of Bruce to the Royal Society that *Trypanosoma* was present in the cerebro-spinal fluid in every one of thirty-eight cases of sleeping sickness investigated in Ugunda, and occurred also in the blood in twelve out of thirteen cases tested on this point.

This species, which has been named *Trypanosoma Castellanii* (see Sambon in *Journal of Tropical Medicine,* July 1st, 1903), closely resembles *Trypanosoma Brucei,* but is said to differ in the following morphological peculiarities: a more or less rounded anterior extremity (posterior extremity of most authors, but this species moves with the more rounded extremity foremost), the centrosome outside the vacuole and much closer to the extremity, the larger vacuole placed before (?) the centrosome, the longer free portion of the flagellum and fewer granules at the posterior extremity.

The transference of the parasite is probably due to some blood-sucking insect, as has been demonstrated for other species of *Trypanosoma;* and in the case of the sleeping sickness, *Glossina morsitans,* the Tsetse fly has been declared responsible by Brumpt. In an illuminating discussion of the subject he shows that the disease is extraordinarily widespread among fishermen on the Congo, and almost unknown among people in the vicinity, who yet do not visit the stream. This accords with the habits of the Tsetse fly, which occurs on the river in immense swarms and is not found a short distance away from it. The freedom from this disease enjoyed by the whites can only be explained on the basis of present knowledge as a type of racial immunity. Recent observations, however, serve to arouse suspicion as to the correctness of the assumption itself.

Although the morphological differentiation of the various species of *Trypanosoma* is difficult, not to say impossible at present, there are sufficient grounds in the clinical features of the diseases caused by them, and in other physiological data, such as the immunity of various host species to certain forms, to justify the acceptance of their specific distinctness. One may well recall the earlier view, that only one form of malarial organism existed, and may find in the transport by *Anopheles* of different species of *Plasmodium* a case parallel to that of the Tsetse fly. Whether the latter host affords the opportunity for the development of a special phase in the life cycle of the trypanosome is as yet purely a matter of conjecture.

The family of the Bodonidæ would not call for any discussion here were it not for the frequence with which certain species have been assigned a rôle as parasites of man. The form which has most frequently been mentioned in this connection is

Cystomonas urinaria (Künstler 1888).—(Syn.: *Bodo urinarius* Künstler 1888; *Cystomonas urinaria* Blanchard 1886; *Plagiomonas urinaria* Künstler of Braun 1895.) Shaped like a beet root (Fig. 5172), 0.01 mm. long, 0.004–0.005 mm. broad, the broad anterior end notched, the posterior end in the form of a long slender filament. Nucleus anterior; two similar flagella originate from anterior notch.

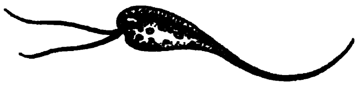

FIG. 5172.—*Cystomonas urinaria.* Magnified. (From Braun, after Künstler.)

In 1856 Hassall described an infusorián which he had observed in alkaline urine that had stood some time open to the air. It was subsequently found in fifty samples of urine from various sources left open similarly, sufficient proof of the contamination. In 1888, however, Künstler reported a form under the same name from fresh urine, which was accordingly attributed to the urinary passages. Blanchard held this to be in reality a new species and renamed it, bringing it in connection with a form described by Salisbury as *Trichomonas irregularis.* Braun regards the latter as rather *Tr. vaginalis*, and distinct from the former, for which he inclines to the view that it was actually a contamination. This is the more probable, as Th. Barrois found many flagellates in "freshly voided" urine in Lille, when subsequent examination yielded no trace of these parasites in urine of the same patients. Evidently the presence of such forms in human urine is beyond question, but their origin from the human urinary passages is yet to be demonstrated. That all such cases require the most searching examination is evinced by a recent experience of my own, in finding objects which were probably much contracted rotifers in preparations made from "absolutely fresh" urine.

The order Polymastigina includes small forms, always non-colonial, with three similar flagella, or with four to eight flagella dissimilar in size and differently located. Two families contain parasitic forms and are distinguished as follows:

Body with three or four flagella, all at anterior end
Tetramitidæ
Body with four to six flagella on anterior end; posterior end either with two flagella, or prolonged into one to three lobes ....Polymastigidæ

In the Tetramitidæ are included species of elongated form with usually pointed posterior end. They have no cuticula, or pellicle, hence may also manifest amœboid movements. One of the flagella may be represented by an undulating membrane. Only one of the genera, *Trichomonas*, embraces human parasites. The diagnosis of the genus may be given briefly as follows:

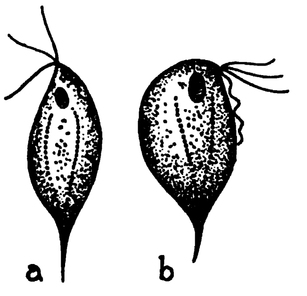

FIG. 5173. — *Trichomonas vaginalis. a*, From osmic-acid preparation; *b*, living. Magnified. (After Blochmann.)

Trichomonas Donné.—Generally pyriform, with anterior end rounded or almost pointed. Posterior end moderately pointed. Nucleus near anterior end, vacuoles near posterior, no contractile vacuole. Either three equal flagella from anterior tip, and also an undulating membrane (*Trichomonas* s. str.), or with three equal flagella directed anteriad, and one much longer extending posteriad from the same point of insertion (sub-genus *Trichomastix*).

Trichomonas vaginalis Donné 1837.—Body very mobile, usually pyriform or spindle-shaped (Fig. 5173), with posterior end sharply pointed and anterior end more or less rounded. The posterior tip is half as long as the rest of the body. Total length 0.015–0.025 mm At anterior pole originate three flagella (four according to other investigators) of equal length, and an undulating membrane which winds spirally about the body to the base of the posterior tip. Plasma finely granular, nucleus near anterior end; posterior to it according to Blochman two longitudinal rows of prominent granules. Division has been reported; encystment is as yet unobserved.

This species is present in females where vaginal catarrh is associated with an acid reaction of the secretion. It has been found in girls of six or seven years and in aged women; and other conditions affect its presence as little as age save that menstruation, alkaline injections, or other conditions which alter the reaction of mucus result in its disappearance temporarily at least. A low temperature (15° C. or less) is also fatal to its existence. Dock and others have demonstrated the presence of this species in the urine of males; the infection doubtless resulted from intercourse and was made possible by an already abnormal condition of the male urethra, as was shown in the cases under discussion. Dock was unsuccessful in infecting guinea-pigs and dogs, and the means of transference from one female to another is unknown. According to Hausmann thirty to forty per cent. of females are infected. The parasites are easily demonstrated in the vaginal mucus, where they move slowly about among epithelial fragments and mucous corpuscles; but for successful demonstration the urine must be examined as soon as passed. Whether their relation to the vaginal catarrh is primary or secondary remains entirely undecided.

Trichomonas intestinalis[*] (R. Leuckart 1879).—(Syn.: *Protoryxomyces coprinarius* Cunningham 1881; *Monocercomonas hominis* Grassi 1882; *Cimænomonas hominis* Grassi 1882; *Trichomonas hominis* Grassi 1888; *Cercomonas coli hominis* May 1891; *Monocercomonas hominis* Epstein 1893.)

Very similar to *Tr. vaginalis* but smaller, measuring 0.004–0.015 mm. in length and 0.003–0.004 mm. in breadth, without rows of granules; posterior end more sharply set off and measuring only one-third the length of the body. Three flagella, the free edge of the undulating membrane has sometimes been interpreted as a fourth. Otherwise as in *Tr. vaginalis*, although the species has not been carefully investigated. Kruse and Pas quale observed groups of individuals which may have arisen by division. Before copulation this species loses its flagella and creeps about with bluntly lobose pseudopodia. This species is ordinarily identified as the *Cercomonas hominis* of Davaine (1854) and the *C. intestinalis* of Lambl (1875), but recent studies have demonstrated the individuality of this from the two cited. There also is a tendency at present to reduce this form to *Tr. vaginalis*, with which it agrees closely, and only an exact study can decide the question. In the uncertainty I regard it as more practical to retain both species, though they are at least closely related.

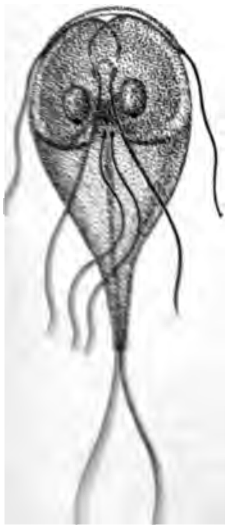
---

[*] This form of the name is probably incorrect, but as the synonymy is badly confused I have retained it pending revision by some specialist.

Tr. intestinalis parasitizes in the anterior and middle regions of the human alimentary canal, and has been repeatedly found in various parts of the world. It occurs also in the oral cavity in decaying teeth, where it nourishes itself on micrococci. It has been reported also frequently from diseased conditions associated with diarrhœa, such as typhoid, cholera, intestinal catarrh, gastric carcinoma, and once in pulmonary gangrene. The species lives only in fluids of an alkaline reaction. Its occurrence in the dejecta of healthy adults has been taken to indicate a commensal rather than a parasitic habit; but it at least multiplies rapidly in connection with morbid processes, and this may exercise an important influence on the progress of the disease. An etiological significance cannot, in the present state of knowledge, be attributed to this species; yet the experiments of Epstein showed that an infection is apparently produced by drinking-water and followed by diarrhœa in children. Experimental infection of animals has not yet succeeded, and the presence of this species in the oral cavity, both in health and in disease, points to possible transport of unknown encysted forms by the air.

Some accounts referred to supposable new species more probably concern this. Such are the forms described by Steinberg from the oral cavity as *Tr. elongata*, *Tr. caudata*, *Tr. flagellata*, as well as perhaps also *Cercomonas biflagellata*, together with the *Tr. pulmonalis* of Schmidt and Artault from sputa or contents of a pulmonary cyst.

The family Polymastigidæ contains small biaxial or bilateral forms with two or three flagella on either side or near the anterior end, while the posterior end is lobed or provided with two further flagella. Only one genus contains human parasites.



[illegible]

Lamblia Blanchard.—At anterior tip one flagellum on each side, and near the centre two on either side; posterior end with two additional flagella. A concave sucking disc (?) on ventral surface near anterior end. Nucleus dumbbell shaped.

Lamblia duodenalis (Davaine 1875).—(Syn.: *Cercomonas intestinalis* Lambl 1859, nec 1875 nec Perty 1852; *Hexamitus duodenalis* Davaine 1875; *Dimorphus muris* Grassi 1879; *Megastoma entericum* Grassi 1881; *M. intestinale* R. Blanchard 1886; *Lamblia intestinalis* R. Bl. 1888; *L. duodenalis* Stiles 1902.)

Length 0.01–0.016 or 0.021 mm.; maximum breadth 0.005–0.007 or even 0.012 mm., with eight flagella nearly equal in length (0.009–0.014 mm.). In form bilaterally symmetrical (Fig. 5174). In ventral aspect it is rounded anteriorly and [illegible] into a very mobile steering tail [illegible] plane. A shallow cordiform ex[illegible] ventral surface near the anterior end cor[illegible] peristome and serves as an organ of attachment; its margin is raised and contractile, but is interrupted posteriorly; all flagella point posteriad; the anterior pair follow the margin half-way around before leaving the body; the lateral pair originate near the anterior margin in the peristome, but are bound to the body until they come to project beyond the contour of the animal; the median pair originate in the notch of the peristome margin and are vibratile through their entire length, being the chief organs of locomotion; the caudal pair are inserted at the tip of the body. The dumbbell-shaped nucleus lies dorsal to the peristome. Contractile vacuole and cytostome are wanting. Division has not been observed; the encysted form is oval, with heavy transparent wall, and measures 0.01 mm. in length by 0.007 mm. in breadth. Schaudinn reports that copulation has been observed and is followed by encystment.

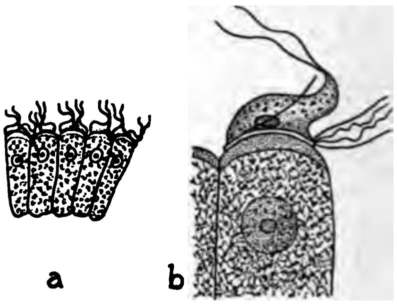


Fig. 5175.—*Lamblia duodenalis.* *a*, On epithelial cells of intestinal villus. × 370. *b*, single cell and parasite. × 1,070. (After Grassi and Schewiakoff.)

This species was first reported by Lambl from the dejecta of children in Prague. It has been reported from Germany, Italy, Russia, Sweden, Egypt, and the United States from the human host in which it seems to be a frequent parasite. It also occurs in rat, mouse, dog, cat, rabbit, sheep, and certain wild species, and is undoubtedly a common and widely distributed parasite.

Its normal seat is the duodenum or jejunum, rarely other parts of the canal, where it sits with the peristome applied to the curved outer face of an epithelial cell (Fig. 5175) on the villi. Although often in such numbers that apparently every cell is occupied, yet no pathological effect has been demonstrated to be exercised by these parasites. Normally only cysts occur in the colon and fæces, but in diarrhœic conditions the free living forms are torn loose and reach the exterior.

Grassi determined by experimental auto-infection that the cysts are the means of infection, and was unable to detect in himself any symptoms incident to the parasitism of the species. It is probable that cereals, or prepared food which becomes contaminated by rats or mice, constitute the ordinary avenue by which the infection of man is brought about.

The class Sporozoa embraces a series of groups of Protozoa of a consistent parasitic habit, which have in common the production at some point in their life cycle of numerous descendants, which are usually covered by a firm shell and accordingly denominated "spores." The enclosed young forms may be single or manifold, and in special cases the cyst wall may be lacking. These young forms always start the life cycle as cell parasites, and in all but rare cases alternation of generations appears in the course of the life history. All forms are true parasites, and all subsist only on fluid nourishment obtained by osmosis.

The class was made by Leuckart in 1879, when he brought together under the heading Sporozoa the imperfectly known and somewhat isolated groups of gregarines (Gregarinida), the psorosperm sacs of Müller (Myxosporidia), the oval or spherical psorosperms of Eimer (coccidia), and Rainey's or Miescher's corpuscles (Sarcosporidia). Later investigators have added the Microsporidia, Amœbosporidia, and Hæmosporidia, and have been able to fill up the gaps in the knowledge of the older groups, so that the association of these forms stands on a much clearer and firmer basis. This is especially true by virtue of the recent discoveries concerning the life cycles of various forms which have revealed an entirely unsuspected complexity and interrelation of the development with the parasitic habit.

In the majority of cases two types of reproduction alternate in the life history of the organism, and this alternation is associated with different factors in the biology of the parasite. The first type subserves the rapid multiplication of the parasite within the host, and is appropriately designated by Doflein multiplicative reproduction; when highly developed it will evidently transform an organism harmless because insignificant into an abundant destroyer of tissue and the exciter of disease. This may be observed again and again in the account of this group. The other type of reproduction is connected with the spread of the species, the infection of new hosts, and may be denoted after Doflein the propagative reproduction. Spore formation is here associated with all sorts of secondary or collateral structures which assist in the transport of the spores, their protection during this period, and their attainment of the new host. The morphology of the propagative reproduction constitutes the means of characterizing the major subdivisions of the Sporozoa; the multiplicative reproduction varies often widely among closely related forms.

The two sub-classes, Telosporidia and Neosporidia, are distinguished by the fact that the former produces spores only at the close of the vegetative period, while the latter do so during the entire period. For the identification of a sporozoon a vegetative stage is rarely sufficient; the form and number of the spores produced during the propagative period of reproduction are characteristic.

In the sub-class Telosporidia one may distinguish two orders on the basis of the habit of the parasites and the mode of fertilization which prevails. Thus in the Coccidiomorpha the vegetative stage is permanently intracellular, while the sexual generation may be so only transiently. The fertilization is anisogamous, *i.e.*, the fusion of differently formed gametes. In the Gregarinida on the other hand, the vegetative stage is intracellular only at the start, as the adult organism is extracellular and the sexual generation also. The fertilization is isogamous, *i.e.*, the fusion of equal and similar gametes. Under the order of the Coccidiomorpha are included forms which until recently have been treated as much more distinct. But more careful study, particularly of the life history, has shown an increasing degree of likeness until they are now included in the same order, and mutally opposed to the Gregarinida in the specific cell parasitism, and in a similar alternation of generations and of hosts in addition to the features pointed out in the outline of the system given above. The features which serve to distinguish the two sub-orders of the Coccidiomorpha are these: The Coccidia produce sporozoites encased in sporocysts, with the exception of *Legerella*, the copula is non-motile and remains in the cell. In the Hæmosporidia the sporozoites are always free, the copula is an active ookinet, and migrates to a new location before undergoing further development.

The adult Coccidia occur as parasites in epithelial cells, particularly of the alimentary canal and its adnexa, though the excretory organs, the male sexual organs, and most recently the spleen are also reported as affected. While the protoplasm of the host cell is ordinarily the seat of the parasite, there are not wanting such as occur in the nucleus itself. Only rarely is more than a single parasite found in an epithelial cell.

In form the Coccidia are uniform and constant, being spherical, oval, or elliptical, and without organs of locomotion of any sort or organs of attachment. Their size is regularly insignificant. A noteworthy characteristic is the absence of differentiation into ectoplasm and endoplasm. The plasma of the cell is finely granular, alveolar, and without reserve bodies or food vacuoles. The nucleus is large, vesicular, and characterized by a single prominent central nucleolus. No contractile vacuole is present, and no further structural differentiations can be noted. The cell and nucleus increase gradually in size at the expense of the host cell, which ultimately in most cases degenerates to a mere empty membrane encircling the coccidium.

The nucleus of the now full-grown parasite undergoes multiple division, the protoplasm arranges itself in individual masses about the many daughter nuclei, and there results a stage in which a rosette of young forms (Fig. 5176) encircles a central portion of protoplasm, known as the reliquary body or residual mass. This is without nuclear matter and destined to play no further part. It is left behind, and perishes when the young forms wander out to infect new epithelial cells of the same host, and repeat the process just sketched. This is evidently the multiplicative reproduction already referred to. It serves to effect the auto-infection of the host, and is generally known as the period of asexual reproduction or schizogony. The cell parasites which undergo these changes are schizonts, while the young forms are denominated merozoites. The merozoites are capable of active movements by contraction and twistings, or with a gliding movement, in which a trail of mucus is left behind. The growth of merozoites to schizonts in the epithelial cells, the production of new merozoites, and the infection of new cells proceed often with considerable rapidity, but only within certain limits, for a new type of reproduction intervenes.

In this which regularly begins under the pressure of excessive infection of the host, the merozoites develop not to schizonts, but to forms of two sorts, which at first sight are very similar to schizonts, and but little different from each other. The one form is opaque with a richly granular plasma; the other has a clear but dense plasma. The opaque form is the female gamete, or macrogamete, and attains maturity by the rejection of a portion of its nuclear substance. The clear cell, known as a microgametocyte, undergoes multiple nuclear division. The many nuclei produced then migrate to the surface, each collects a small part of the plasma about itself, and projects as an elongated spindle-shaped structure, the microgamete or male cell, which becomes free, forms two flagella, and enters upon active locomotion. The major portion of the microgametocyte is abandoned, and subserves no further function.

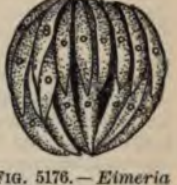

FIG. 5176.—*Eimeria Stiedæ.* Adult Schizont Completely Divided into Merozoites. Cyst formed of degenerated host cell is not represented. Magnified. (After Simond.)

The microgametes swarm about the macrogametes, and as soon as one has succeeded in entering, the macrogamete forms at once a firm membrane, which forbids entrance to other microgametes. The two nuclei unite and the act of fertilization is completed. The product is known as an oocyst, copula, or sporont, and forms the starting-point of a new period in the life cycle, which is that previously designated as the propagative reproduction. It is also known as the sexual spore-forming period, or sporogony, and in most coccidia takes place outside of the host, after the oocyst has been evacuated in fæces or urine. The steps in the process of sporogony may be outlined next in general terms (Fig. 5177).

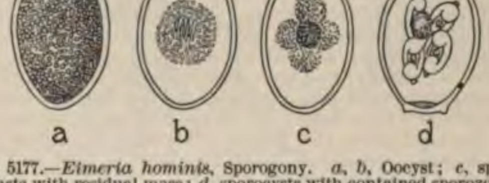

FIG. 5177.—*Eimeria hominis*, Sporogony. *a*, *b*, Oocyst; *c*, sporoblasts with residual mass; *d*, sporocysts with contained sporozoites. Magnified. (From Braun after Riek.)

The nucleus of the oocyst (*a*) divides twice, and about the four daughter nuclei the protoplasm separates into four parts known as sporoblasts (*b*), and sometimes also a residual mass of protoplasm (*c*). Each of these sporoblasts surrounds itself with a firm membrane and becomes a sporocyst (*d*), while later within each sporocyst after nuclear division two sporozoites are formed and a residual mass of protoplasm is left unused. The sporozoites are characteristically sickle-shaped or crescentic, and abandon the sporocyst when this reaches the alimentary canal of the new host, and is opened by the action of the alimentary secretions. The entrance of the sporozoites into the epithelial cells and their growth to schizonts completes the life cycle.

This typical course of development is well represented by the tabular outline given by Lühe and reproduced here. The stages connected by a single vertical line (|) are successive generations in the life cycle; those connected by the sign of equality (=) are produced by growth or metamorphosis within the single generation.

Development of Eimeria.

Schizogony (oft repeated).

etc. (Schizogony soon ceasing).	= ♀ Macrogamete.	♂ Microgamete.	= ♀ Macrogamete.	♂ Microgamete.	etc. (Schizogony soon ceasing).

Sporogony.
Copula = Sporont (Oocyst).
|
Sporoblast = Sporocyst.
|
Sporozoite = Schizont.

This general plan of development is modified in the individual species in various manner. The most striking modification is a simplification by suppression of the entire schizogonic cycle, so that the macrogametes and microgametocytes arise directly from the sporozoites which have penetrated epithelial cells.

The coccidia parasitize almost all groups of the animal kingdom, and are distributed over the entire world, although, as might be expected, the majority of reports thus far made concerning their presence come from European countries.

For the subdivision of the group Léger's proposal to use the number and form of the sporocysts and of the sporozoites has been generally adopted. The adjoined table gives a review of the common genera arranged according to Léger's scheme.

Ripe oocyst contains	Numerous sporozoites	No sporocysts. ASPOROCYSTIDEA		Legerella.
		Many sporocysts each with POLYSPOROCYSTIDEA.	One sporozoite	Barroussia.
			Two sporozoites	Adelea.
			Three sporozoites	Eucoccidium.
			Four sporozoites	Klossia.
	Eight sporozoites	Two sporocysts each with four sporozoites. DISPOROCYSTIDEA		Isospora.
		Four sporocysts each with two sporozoites. TETRASPOROCYSTIDEA		Eimeria.
	Four sporozoites	Two sporocysts each with two sporozoites.		Cyclospora.

Some confusion has prevailed regarding the correct names of the various genera. The original cause of this difficulty rests on the fact that the two phases of the life cycle, schizogony and sporogony, were discovered and named separately, and that their relations as parts of the development of a single species did not become known until a much later date. All of the human parasites thus far recorded from this group fall within the limits of a genus named *Coccidium* by R. Leuckart in 1879, and this name has been generally incorporated into works on the subject. At a very recent date, however, Stiles and Lühe have independently called attention to the fact that the name *Eimeria*, introduced in 1875 by Aimé Schneider, has the right of priority, and must replace the more common form according to laws of zoological nomenclature. This is really fortunate from the general standpoint since the name coccidia has been very generally used for the entire group as well as heretofore for the genus; yet this is not in the interest of precision, and may evidently lead to serious misunderstanding. Henceforth the name coccidia can be used only in the more general sense.

The genus *Eimeria* is the best known of all. Its most important characteristic is the formation in each oocyst of four sporocysts, each with two sporozoites. A residual mass of protoplasm is always present in the sporocyst with the sporozoites, and a similar residual mass is sometimes formed in the oocyst with the growth of the sporoblasts. Of the many species assigned to this genus, the most important and better known forms which are pathologic to man and some domestic animals are included in the following key:

1. Oocyst with residual mass.... 2
1. Oocyst without residual mass........ 3
2. Oocyst oval, 33–49 μ by 16–28 μ; sporocyst spindle-shaped (rabbit, man)..................*E. Stiedæ* (Lind.)
2. Oocyst spherical or cylindrical, 15–32 μ by 11–17 μ; sporocyst oval (mouse)........*E. falciformis* (Schuberg)
3. Simple forms. Oocyst oval to cylindrical, 24–35 μ by 13–20 μ. ....*E. hominis* (Riv.)
3. Twin forms...................*E. bigemina* (Stiles)

Eimeria Stiedæ (Lindemann 1865).—(Syn.: *Monocystis Stiedæ* Lindemann 1865; *Psorospermium cuniculi* Rivolta 1878; *Coccidium oviforme* Leuckart 1879; *C. cuniculi* Raillet 1893; *Pfeifferia princeps* Labbé 1896; *Pfeifferella princeps* Labbé 1899. *Eimeria cuniculi* Lühe 1902.)

All stages are known. Oocyst (Fig. 5178) in the liver of rabbit, oval 0.033–0.049 mm. long, 0.015–0.028 mm. broad. Cyst wall heavy, smooth, with opening at one pole. The coarsely granular protoplasm completely fills the cyst, but later contracts to a spherical mass at the centre (0.017 mm. in diameter). Spore formation outside the host requires two to three weeks. The entire sphere divides into four sporocysts each with a thick covering and with a length of 0.012 to 0.015 mm. and a breadth of 0.007 mm. Two comma-shaped sporozoites are formed in each sporocyst, and a granular residual mass of protoplasm lies in the hollow between their enlarged ends (Fig. 5179). The sporozoites are set free by gastric digestion. They ascend the gall ducts, pene-

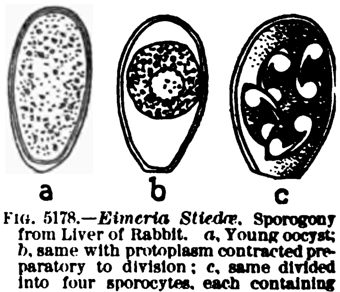

FIG. 5178.—*Eimeria Stiedæ*. Sporogony from Liver of Rabbit. *a*, Young oocyst; *b*, same with protoplasm contracted preparatory to division; *c*, same divided into four sporocytes, each containing two sporozoites which have already developed. Magnified. (*a*, *b*, after Leuckart; *c*, after Simond.)

trate the epithelial cells, and when fully grown measure 0.02–0.05 mm. in length by 0.02–0.039 mm. breadth. They divide into from 30 to 200 merozoites (Fig. 5176) which spread the infection. Ultimately the formation of macro- and microgametes leads to the fertilized sporont stage, the oocyst.

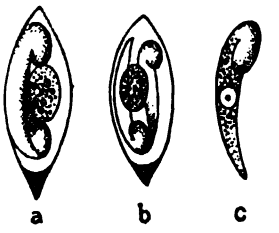

FIG. 5179.—*Eimeria Stiedæ.* *a*, *b*, Sporocysts each with two sporozoites and residual mass; *c*, a single sporozoite. Highly magnified. (From Railliet, after Balbiani.)

This species is an abundant parasite of the rabbit, in which it parasitizes in the epithelium of gall ducts and liver. According to the degree of infection sooner or later inflammation and proliferation of the epithelium lead to the formation of nodules of caseous matter, containing amid various remnants coccidia in all stages of development. These conditions may lead to severe sickness or even to the death of the host; in other cases the animal recovers as the process of schizogony appears to have distinct self-limitations. The infection is spread by the contamination of food with spore-infected fæces.

Several cases of human infection are on record. Evidently conditions favor such infection only rarely. To the four positive cases cited by Leuckart, all in Germany and Austria, Silcock has added another from London. A number of doubtful cases are also included here by some authorities. The observations of Thomas in Boston, according to which this species was found in a small cerebral tumor surrounded by bone tissue, has little to support the diagnosis in view of the normal condition of the liver and intestine, and has been universally questioned by reviewers. In any event the supposed coccidia cannot belong to this species, or any other yet reported from man, on account of their size (0.014–0.022 mm. in length). They correspond, however, in size nearly to the coccidia reported by Stiles from sheep which belong to a species as yet unnamed. More probably they are not coccidia at all.

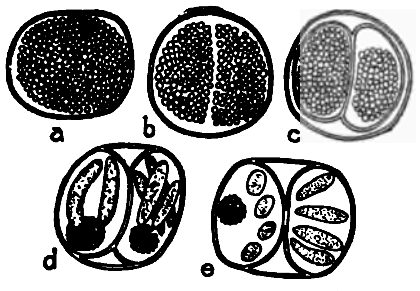

FIG. 5180.—*Eimeria bigemina*, Sporogony. *a*, *b*, *c*, Division into two masses; *d*, *e*, formation of sporoblasts with residual mass. Highly magnified. (After Stiles.)

Eimeria hominis (Riv. 1878), nec. R. Blanchard 1895.—[Syn.: *Cytospermium hominis* Rivolta 1878; *Coccidium perforans* R. Leuckart 1879; *C. hominis* Railliet 1893; *Pfeifferella princeps* (Labbé 1899) in part.]

Oocyst (Fig. 5177) 0.024–0.026, or even 0.035 mm. long by 0.0128–0.014 or even 0.02 mm. broad, plumper than those of *E. Stiedæ*, from which also they differ in the constant presence in sporulation of a residual mass of protoplasm that is said to be constantly absent in the latter species. (Compare Figs. 5177 and 5178.) Here also only three to four days are necessary to bring the division of the contents of the oocyst into sporoblasts (sporocysts).

This species, which is so closely related to *E. Stiedæ* that many authors regard them as identical, parasitizes in the intestinal epithelium of the rabbit, where it evokes serious, often fatal epidemics. Railliet and Lucet have demonstrated that infection takes place by the ingestion of ripe spores, and rapid schizogony brings about in a few days serious auto-infection involving the epithelium and Lieberkühn's glands so as to occlude the latter. The forms found in horse, goat, cattle, sheep, pig, and other wild species are usually regarded as varieties, but the considerable differences in form and size make it more probable that some at least represent distinct species.

Eimer found in two bodies examined in Berlin the epithelium of the intestine filled with coccidia, and even in large part destroyed by them. These are probably referable to this species. Other authors have reported the discovery of coccidia in human fæces at various times without furnishing data for the determination of the species concerned.

Eimeria bigemina (Stiles 1891).—(Syn.: *Cytospermium villorum intestinalium canis et felis* Rivolta 1874; *Coccidium bigeminum* Stiles 1891.)

Oocyst (Fig. 5180) 0.012–0.015 mm. by 0.007–0.01 mm. (in dog), or 0.008–0.01 mm. by 0.007–0.009 mm. (in cat), or 0.008–0.012 by 0.006–0.008 mm. (in polecat). The oocyst divides into two parts, each of which encysts and forms four sporocysts. The oocysts occur not in the epithelium, but in the central tissue of intestinal villi (Fig. 5181).

The species was first seen as early as 1854 by Fink, who, however, misinterpreted the character of the objects. It has often been confused with *E. hominis*, from which the above characteristics easily distinguish it. A case of human infection, published by Virchow in 1860, and another by Grunow in 1901, very probably belong here. The description given by Railliet and Lucet of coccidia discovered in the fæces of a mother and child who had long suffered from chronic diarrhœa corresponds well with this species in the small size of the bodies found, and is also probably referable to it. The form is evidently only an occasional parasite of man, and infection probably results from lack of cleanliness or too intimate association with pet dogs or cats. It may be that the forms discussed as varieties from different hosts actually represent different species. Stiles has found this species in dogs killed in Washington, D. C.

It is not surprising in view of the imperfect acquaintance with this group that all sorts of questionable structures should be referred to it. They are all such as have been reported from man usually in connection with some abnormal condition, and frequently also on the basis of a single occurrence. In most cases only scanty data are given concerning the supposed coccidia, and even of the best known of these problematic structures too little can be said to determine their true nature or position in the zoölogical scheme. It is best to call attention to certain of these cases briefly, in order that if possible further data should be accumulated to elucidate their real character. Perhaps the most sporozoon-like of all are bodies described by Rixford and Gilchrist from two cases studied at the Johns Hopkins Hospital in 1897; their characters so far as known do not easily permit of their classification in the coccidia (s. str.).

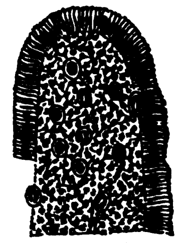

FIG. 5181.—*Eimeria bigemina* in Transsection of Villus from Intestine of Dog. Highly magnified. (After Stiles.)

Coccidioides immitis Rixford and Gilchrist 1897.—(Syn.: *C. pyogenes* Rixford and Gilchrist 1897.)

Unicellular spherical bodies from 0.007 to 0.035 mm. in diameter.* So-called capsule thick, doubly contoured, enclosing a finely granular protoplasm with a clear zone [ectosarc?], 0.002–0.003 mm. wide, between capsule [pellicle?] and contents. No vacuoles seen; nucleus not demonstrated. Position of parasites usually intracellular, sometimes, however, extracellular. Sporozoites [merozoites?] approximately one hundred in a capsule, 0.001–0.002 mm. long.

---

* The authors give the size of the adult (p. 229) as 15 to 27 μ; again in the diagnosis (p. 243) as 16 to 30 μ, and finally in their summary (p. 246) as 7 to 27 μ. In the second case the parasites are given as 20 to 35 μ in diameter.

Found primarily (?) in the skin, later generally throughout internal organs also. Reported from California and Buenos Ayres. All cases reported concern males of thirty to forty years of age.

In the first case the disease first appeared on the back of the neck and spread very slowly, causing death in about ten years. It was only very slightly contagious, if at all, as beyond the original sores new lesions appeared only in two spots on the patient's body, and none of those who came in contact with him are known to have become infected. Some inoculation experiments were successful, but no cultures. The cutaneous lesions resembled tuberculosis cutis in character, being the seat of genuine caseation or coagulative necrosis. Both to the naked eye and microscopically the nodules were indistinguishable from tubercles save that they contained the protozoa and did not contain tubercle bacilli. In the opinion of the discoverers this seems to indicate the power to produce toxic products which possess pyogenic properties, causing both the local lesions and general symptoms. From the fact that the whole alimentary canal and mesenteric glands remained normal throughout the course of the disease, the authors exclude the supposition that the parasites entered the system through the digestive tract. The parasites were particularly abundant in the caseous foci, and occurred in far greater numbers in the lesions of the internal organs than in the cutaneous lesions. Often these parasites were found in multitudes in giant cells. They were searched for in vain only in the membranes and substance of the brain.

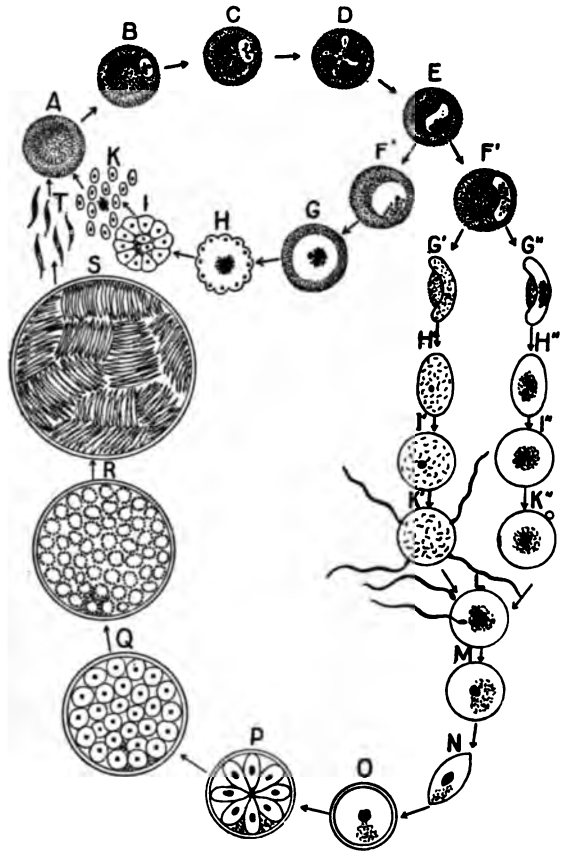

FIG. 5182.—Development of *Plasmodium immaculatum*. *A*, *E*, *G*, *K*, Schizogony in human blood; *F'*, *L*, formation of gametes and fusion of same; *M*, *S*, *T*, sporogony in mosquito. Somewhat diagrammatic. For further details see text. (After Neveu-Lemaire.)

Another case was reported by the same authors, and like the first occurred in a native of the Azores, who had been resident in California for a number of years. The disease was acute rather than chronic as in the first; and was very destructive as the patient lost both eyes, the nose, and much of the lip, and one ear in the course of three months. According to the authors the parasite was a different species, but the distinctions are insufficient to warrant a separation of the two in our present state of knowledge. The authors identify with their cases a third, reported by Wernicke in 1892 from Buenos Ayres. Wernicke gave only an incomplete description of the parasite, and regarded the cutaneous affection as a mycosis fungoides. The protozoa he found measured from 7 to 80 μ in diameter.

There are other reports of less definiteness than those just considered, and some of the questionable structures noted therein have found an explanation within recent times. Thus the psorospermcysts of Lubarsch and Ribbert, which were supposed to play a part in diseases of the urinary passages, are in reality metamorphosed nests of epithelial cells normally found in the urethra. The structures found by Künstler and Pitres in pleural exudate and interpreted by Blanchard as a sporozoon, *Eimeria hominis* R. Blanchard 1895, I have preferred to interpret as *Echinorhynchus* eggs (*Cf. Nematoda*, page 225). More uncertain still are Severi's "monocystic gregarines" from the lung parenchym of a still-born child. They are described as oval in form, exceedingly variable in size (0.003–0.03 by 0.0015–0.015 mm.), covered by a thin membrane, and either free or in epithelial cells; it is difficult to interpret them in any satisfactory manner. Some of these doubtful structures are discussed as appendices to the next sub-order, the Hæmosporidia, to which they show a certain similarity.

An error of the reverse type is that frequently made in the past of diagnosing eggs of parasites as coccidia. Thus nematode eggs have once been reported as coccidia, and eggs of trematodes many times. Were it not for the extremely small size of the structures described, the case of J. J. Thomas, noted above, concerning coccidia in a brain tumor would find its easy explanation in this same manner.

The Hæmosporidia, like the Coccidia, are characteristic cell parasites. The period of schizogony or multiplicative reproduction is passed in the blood cells, and only very exceptionally in the cells of other organs. These stages have long been known, and with them a few preparatory stages to the sporogonic cycle, although the latter have been entirely incorrectly interpreted as degenerative changes, etc. So far as is known this sporogonic cycle takes place only in the body of another host; and for the Hæmosporidia of mammals and birds this host is a blood-sucking insect in which the process of sporogony is carried out in the wall of the alimentary canal, and the sporozoites collect in the salivary glands, whence they are injected by the act of biting into a new host to start anew the schizogonic cycle. The close relationship of these forms to coccidia is evident from a study of the life history, as Doflein indicates most aptly in calling them coccidia adapted to parasitism in the blood system.

The life history may be outlined from that of the æstivo-autumnal parasite (Fig. 5182). The earliest stage of the parasite which occurs in the erythrocytes is a minute amœboid body (*A*) which increases rapidly in size, manifesting considerable amœboid activity (*B*–*E*). In connection with the growth of the organism particles of a black pigment matter, named melanin, are stored up in its protoplasm (*F*, *G*). The nucleus of the parasite, at first single, begins to divide rapidly when the organism has reached its maximum size and the daughter nuclei collect about the rim of the organism (*H*). Radial lines of division appear in the protoplasm (*I*), and the whole falls into a group of young germs or merozoites (*K*) about a central residual mass of protoplasm loaded with the pigment already referred to. The merozoites infect new blood cells, and the process of schizogony is repeated until conditions, as yet unknown, bring in a new set of changes, the starting-point of another cycle, the sexual phase, or sporogony.

The merozoites develop to individuals differently formed from the schizonts and of two sorts, the one finely granular and opaque (*G″*), the other hyaline in appearance with a few conspicuous pigment granules (*G′*). These forms are shaped like a bean in the species under consideration, and are those previously designated as half-moon or crescentic bodies. When fully grown they desert the corpuscle (*H′*, *H″*) assume a spherical form (*I′*, *I″*). The macrogamete extrudes a portion of the nuclear substance (*K″*) and is mature. The nucleus of the microgametocyte divides, the parts migrate to the surface and form microgametes by a small accumulation of plasma about each (*K′*), leaving a large central residual mass. These two gametes copulate, their nuclei fuse, and the product (*M*) is the starting-point of the sporogonic cycle, the sporont.

The changes leading to the perfection of the sexual cells take place only after the blood has been drawn into the stomach of the new host, the blood-sucking insect. Abnormal stimuli may, however, bring about some of the changes, as in cultures of malarial blood. The copula acquires an amœboid form (*N*) necessary for its attainment of a location within the tissue of the new host. This motile stage, which has been denominated the ookinet, is a gregarine-like organism, and penetrates an epithelial cell, where it transforms itself into an immobile spherical oocyst (*O*). After nuclear division there are formed in the oocyst numerous sporoblasts (*P*, *Q*), which, however, never acquire a heavy membrane, *i.e.*, never become sporocysts as in the coccidia. Each sporoblast gives rise to a large number of sporozoites (*R*, *S*), which are set free into the body cavity of the insect host by the rupture of the wall of the oocyst. They collect as the result of an evident chemotactic influence in the salivary gland, and are injected into a new host when the insect bites. There they enter the erythrocytes and the life cycle begins anew.

The organisms included in this sub-order are the cause of serious diseases, and their number is being rapidly increased by the investigations of most recent times. Many doubtful forms have also been placed temporarily under this heading, so that it is impossible to give a synopsis of the genera, or to fix the precise limits of the sub-order itself.

Most prominent of the forms which are included here are the parasites of human malaria. Grassi still regards these all as merely varieties of one species. This is clearly doing violence to the ordinary zoological significance of the word. On the other hand, several investigators have grouped them into two genera, a plan which I myself followed in an earlier paper. Here they will be treated as three species of one genus in accord with a recently expressed view of Schaudinn, and with the known facts regarding their clinical manifestations, structural differences, and life histories.

The genus *Plasmodium* includes in addition to these species the parasite of avian malaria also. It was established in 1885 by Marchiafava and Celli, and although the name is employed here in a sense utterly at variance with its meaning as a term in general scientific use, yet the rules of zoological nomenclature call for its retention. The malarial organism was first seen and figured by Klencke in 1848 without any idea of the significance of the structures viewed. Laveran in 1880 was the first to attach etiologic significance to the structures he described from the erythrocytes in cases of malaria. A large number of investigators participated in the gradual elucidation of the schizogony of these parasites. It was 1896, however, before Manson set forth distinctly the agency of the mosquito in transmitting the disease. Just a year later Ross actually followed for the first time the fate of the parasites of avian malaria in the mosquito's stomach, and their development up to the infection of a new host by the sporozoites. Ross' observations on avian malaria were confirmed soon after by Grassi and other Italian investigators for human species of the malarial parasite.

The complicated terminology in this group, due to the continual changes introduced by various investigators, renders it advisable to give here for general information the table prepared with such success by Lühe, which shows the correspondence in the nomenclature of the chief investigators of recent date. The terminology of Schaudinn, which is followed in this article, has been more generally adopted than any other, and has much in favor of it from every standpoint. (See table below.)

The extensive consideration which the subject has received in previous articles in the REFERENCE HANDBOOK (compare *Malaria*, *Mosquito in Relation to Human Pathology*, *Plasmodium Malariæ*) renders it necessary here only to insert a brief diagnosis of the three species, and refer to the articles noted for further details.

1890; *Hæmamœba malariæ* Grassi et Feletti 1892; *H. Laverani* var. *quartana* Labbé 1894; *Pl. malariæ quartanum* Labbé 1899.)

Young form in erythrocyte small, unpigmented; movement slow; pigment in coarse granules, first visible in about twenty-four hours, and peripheral in position. Movement decreasing until in sixty hours after the attack, or twelve hours before the next, the spherical *Plasmodia* fill almost the entire corpuscle. Having reached a diameter of about 0.007 mm. schizogony begins, and nine to twelve (rarely six or fourteen) merozoites are formed which are very regular (Fig. 5183, *e*). The melanin granules move in radial lines and collect in the central residual mass, from which the merozoites separate themselves in seventy-two hours. The synchronous release of these germs brings another paroxysm at this time, whence the name of quartan fever for the disease induced by this species, which is also often designated the quartan parasite. The gametes are few in number, spherical, and characterized by active streaming in the protoplasm. The sporogony of this species in *Anopheles* goes on at a minimum of 16.5° C., and stops before the maximum of 30° C. is reached. *Plasmodium malariæ* is found farther north than either of the other human malarial parasites, but does not extend into the tropics.

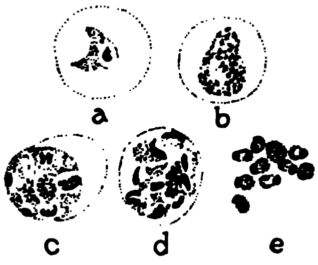

FIG. 5183.—*Plasmodium malariæ*, Schizogony. *a*, *b*, Growth of schizont; *c*, nuclear division; *d*, formation of merozoites; *e*, release of same by destruction of erythrocyte, residual mass at upper side of group. Magnified. (After Bastianelli and Bignami.)

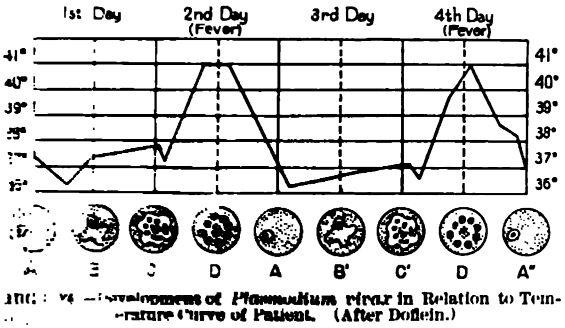
Plasmodium vivax (Grassi et Feletti).—(Syn.: *Hæmamœba vivax* Gr. et Fel. 1892; *Pl.* var. *tertiana* Golgi 1889; *H. Laverani* var. *tertiana* Labbé 1894; *Pl. malariæ tertianum* Labbé 1899.)

Young stages in the erythrocytes are very active. Pigment granules are fine, and light brown in color. The fully grown schizont completely fills the red corpuscle, which is usually swollen and bleached in color. This stage measures 0.008–0.01 mm. in diameter, and produces fifteen to twenty merozoites in schizogony, which requires for its completion just forty-eight hours, whence the common names of tertian fever and tertian parasite. The pigment forms a solid mass in the centre, and the merozoites form a double ring about it, or more frequently an irregular mass. Schizogony occurs preeminently in the spleen. The gametes are abundant at a certain period, of spherical form, and distinguished from



[illegible]—Development of *Plasmodium vivax* in Relation to Temperature Curve of Patient. (After Doflein.)

di[illegible] pa[illegible]

The pa[illegible] above all in the form of the pigment, which foci, and [illegible] granules or bacilliform masses. They reach of the [illegible] times the diameter of an erythrocyte. The Often these [illegible] the body of *Anopheles* requires eight days cells. They [illegible] of 25°–30° C.; 17° C. is the minimum branes and [illegible] unknown. This corresponds to the occurrence of the disease in the tropics and subtropics. The relation of the body temperature of the host to the development of the parasite is well shown in the accompanying diagram (Fig. 5184).

Plasmodium immaculatum (Grassi et Feletti).—(Syn.: *Laverania malariæ* Gr. et Fel. 1890; *Hæmamœba malariæ præcox* Gr. et Fel. 1892, nec. *H. præcox* Gr. et Fel. 1890. *Hæmamœba immaculata* Gr. et Fel. 1892; *Plasmodium præcox* Doflein 1901.)

This is the smallest of all human malarial organisms. Fully grown schizonts measure only 0.005 mm. in diameter. Young form very active; pigment moderate in amount, very fine in peripheral zone. The schizont may also remain unpigmented, and this form has been regarded as a separate variety. Multiple infection of an erythrocyte is not rare, and the assumption of a signet-ring form is very common. The erythrocyte shrinks during the growth of the parasite. In schizogony seven, ten, or twelve merozoites are formed, rarely twelve to fifteen, and these are small, being only 0.001–0.0015 mm. in diameter. The length of the schizogonic cycle is not well determined, as the process takes place in internal organs, especially the spleen. It is apparently irregular, though forty-eight hours seems most probable. The gametes are crescentic or reniform, and originate especially in bone marrow. Further changes have been most carefully followed in this species. In the stomach of *Anopheles* these crescents become spherical (Fig. 5185) and the microgametes are formed and set free. The fertilization is completed by the fusion of a single microgamete with a macrogamete; and the resulting motile ookinet (Fig. 5186, *a*) penetrates the wall, entering first an epithelial cell and coming later to lie between the layers of the wall (Fig. 5186, *b*). The oocyst forms no special covering, but increases rapidly in size. Sporoblasts and then sporozoites are formed; the latter have a length of 0.014 mm. and a thickness of 0.001 mm., and are produced to the number of ten thousand in a single oocyst. After the rupture of the latter they accumulate in the salivary gland, lying in the secretion either within the cells or in the duct itself, whence they are expressed in the act of biting (Fig. 5187).

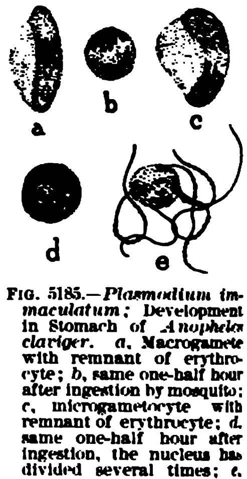


FIG. 5185.—*Plasmodium immaculatum*; Development in Stomach of *Anopheles claviger*. *a*, Macrogamete with remnant of erythrocyte; *b*, same one-half hour after ingestion by mosquito; *c*, microgametocyte with remnant of erythrocyte; *d*, same one-half hour after ingestion, the nucleus has divided several times; *e*, microgametes still attached to residual mass (so-called polymitus stage). Highly magnified. (From Braun, after Grassi.)

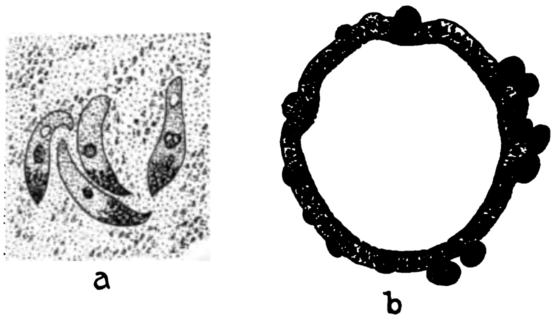

FIG. 5186.—*Plasmodium immaculatum*. *a*, Ookinet in stomach of *Anopheles claviger* thirty-two hours after ingestion; *b*, transsection of stomach with partly developed oocysts several days later. Magnified. (From Braun, after Grassi.)

The sporogony requires eight days at a temperature of 28°–30° C., and 18° C. is the minimum temperature for the infection of *Anopheles*. This species gives rise to the malarial fever designated as æstivo-autumnal, perniciosa, tropica, etc., and is epidemic only in the tropics and subtropics. This is the form which has been rated as a representative of another genus, *Laverania malariæ*, by

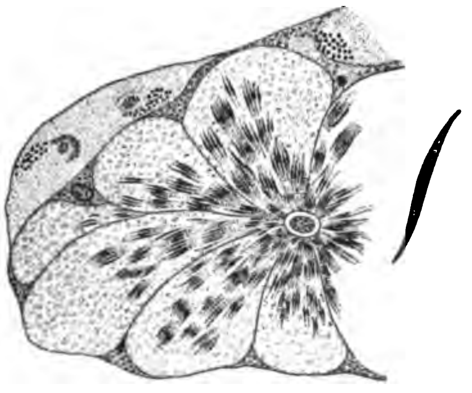

FIG. 5187.—Section Through Dorsal Sac of Salivary Gland from *Anopheles* with Groups of Sporozoites of *Plasmodium immaculatum* both in gland cells and in duct. Isolated sporozoite at right more highly magnified. (From Lang, after Grassi.)

many observers. While its separation from the genus *Plasmodium* is perhaps a convenience, it seems hardly justifiable on scientific grounds, as the differences between it and the other species are not of generic rank.

Uncertain Species.—According to the work of certain investigators, particularly Celli, there exists a true quotidian malarial parasite, which is related to *Plasmodium immaculatum*, although smaller and completing the schizogony in twenty-four hours. The supposed species is found in Italy particularly in summer and fall, and is regarded by most authors as at most a variety of *Pl. immaculatum*. Still other forms from tropical regions have been regarded as distinct species without sufficient evidence as yet for this opinion.

There are yet other hæmatozoa of which it may be said that their exact relationship has not been sufficiently demonstrated to give them a definite place in the system, but which in all probability will be included in this suborder, though evidently not in the same genus with the malarial organisms just described.

In this connection should be noted the parasite of the spotted fever or tick fever of the Rocky Mountains, a new disease especially virulent in the valley of the Bitter Root River in Montana, where it has been known for twenty years, but present apparently also, though in milder form, in other parts of Montana, Idaho, Wyoming, Nevada, and Eastern Oregon.

Wilson and Chowning were the first to note ovoid intracapsular bodies in stained blood preparations, and to determine that in fresh blood these bodies manifest amœboid movements. These observations have been confirmed by later investigators, and the hæmatozoon is regarded by all as probably the cause of the disease. A brief description of the organism may be given here.

The smallest forms, or the first phase of Wilson and Chowning, are intracellular, ovoid bodies and measure 0.0015-0.002 mm. in length by 0.0005 to 0.001 mm. in thickness. They resemble slightly young schizonts of malaria, and more strongly the organism of Texas fever of cattle. These bodies occasionally change position in the corpuscle, and according to Anderson project pseudopodia quite rapidly. Two such bodies may lie in a single corpuscle. In the second phase the bodies are solitary in the erythrocytes, oval, ellipsoidal or spherical in form, and from 0.002 to 0.003 mm. thick by 0.003 to 0.005 mm. long. This phase is actively amœboid with the formation of pseudopodia in various directions. The third phase is seen in pyriform bodies arranged in pairs with the pointed ends approximated, and in rare cases distinctly united by a fine thread. This form is not amœboid.

Though the parasites are not found in large numbers in the circulating blood, only a few being present in each field of a preparation of freshly drawn blood, yet in the capillaries of tissues removed at autopsies from one to five per cent. of the erythrocytes are infected. This is marked in the lung, spleen, liver, and kidney, where also are found many red cells included in phagocytes, being faintly outlined within the protoplasm of the latter, and each containing a large parasite. In tissues taken some hours after death, the organisms are almost all spheroidal. They are present in the blood at least twenty-four days after recovery.

The organism is apparently transmitted by ticks, and all cases of the disease show a history of tick bites about one week before the onset. Stiles made a provisional determination of some ticks from the region as *Dermacentor reticulatus* but in correspondence later expressed the view that certain differences though slight justify placing these forms in a new species. Some facts point to the existence of another normal mammalian host for the parasite, and the gray gopher has been indicated as the most probable form. Further study is necessary to establish the character and development of this parasite, its exact systematic position, and its positive relation to the disease. Its superficial resemblance to *Piroplasma bigeminum*, the cause of Texas fever in cattle, has already been mentioned.

Myxococcidium Parker, Beyer, Pothier 1903.—Schizogony unknown; sporogony in *Stegomyia fasciata*. Only one species, thus far imperfectly known.

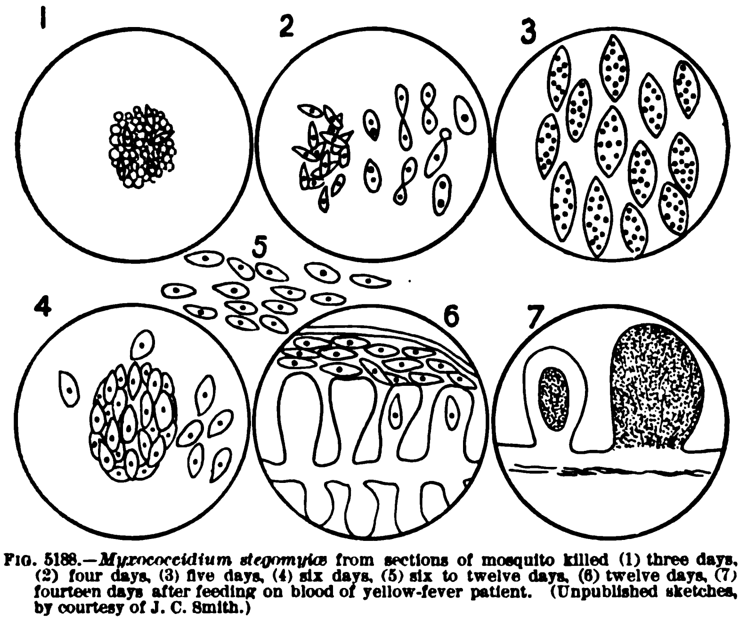

FIG. 5188.—*Myxococcidium stegomyiæ* from sections of mosquito killed (1) three days, (2) four days, (3) five days, (4) six days, (5) six to twelve days, (6) twelve days, (7) fourteen days after feeding on blood of yellow-fever patient. (Unpublished sketches, by courtesy of J. C. Smith.)

Myxococcidium stegomyiæ Parker, Beyer, Pothier 1903 (Fig. 5188).—A fusiform body (ookinet?) 0.003-0.004 mm. long by 0.0015-0.002 mm. broad in lumen of stomach and œsophageal diverticulum, about three days after mosquito has bitten yellow-fever patient; this body is provided with a nucleus. A spherical body (oocyst?) in the œsophageal diverticulum, embedded in an albuminoid mass of unknown character. This becomes mature and breaks up into numerous (thirty to forty) elongated oval bodies (sporoblasts?), 0.003 mm. long by 0.002 mm. broad, which enter the cells of the salivary gland, and then coming to rest (sporocysts), divide into numerous very minute bodies (sporozoites?).

The parasite was found in the yellow-fever mosquito (*Stegomyia fasciata*) from Vera Cruz, Mexico, by Drs. Parker, Beyer, and Pothier, Working Party No. 1, Yellow-Fever Institute of the United States, Public Health and Marine Hospital Service. According to these authors the mosquitoes used were fed on the blood of a yellow-fever patient, and with due precautions against infection from any other source were killed at stated intervals from the second to the thirtieth day. A careful study of sections of these mosquitoes in which the Working Party mentioned received valuable assistance from Mr. J. C. Smith, of New Orleans, resulted in the demonstration of the life history of the organism somewhat imperfectly as outlined above. More recently, however, Carroll has maintained that the fusiform stage is actually a wild yeast.

The Working Party also states that yellow fever was produced experimentally with mosquitoes from a case that harbored this parasite, and the parasite was found again in mosquitoes fed on this case. Furthermore they permitted this same species of mosquito to feed on a case of malarial fever of the malignant type, on normal blood, and on other nutritive materials, and in none of these mosquitoes were found the parasites described above.

From the account given it appears that there was present in these mosquitoes a parasite, the development of which bears close resemblance to that of the malarial organism in the sexual cycle (sporogony). On the analogy of the latter parasite there should also occur in this case a non-sexual cycle (schizogony) in the blood (?) of the yellow-fever patient. Yet Sternberg, Reed, Carroll, and many others have sought in vain for such an organism; nor was the Working Party more successful. The further life history of *Myxococcidium stegomyiæ* lies even beyond conjecture, and it can only be said that negative evidence raises a strong presumption in favor of its etiological relation to yellow fever.

Quite recently Councilman, Magrath, and Brinckerhoff have made known the results of studies on the organisms of vaccinia and of variola, which go far toward establishing the nature of these oft-reported and much-questioned bodies. Much is needed to confirm these reports and to elucidate further details in life history, as well as the general relationship of these bodies. They may be considered briefly here without prejudicing the results of further study on these points. Before vesicle formation in the diseases noted, small, structureless bodies (0.001–0.004 mm. in diameter) occur in vacuoles of cells in the lower layers of the dermal epithelium. With increase in size the body shows granules lying in a reticulum, and becomes irregular in form as if amœboid. No nucleus was demonstrated. Formation of small round bodies, 0.001 mm. in diameter, closes the first stage in the life cycle. Following this oval or ring-like intranuclear bodies appear. In them several vacuoles are seen grouped around a central vacuole. They enlarge and destroy the nucleus, and come to lie in a completely degenerated cell. The vacuoles become less evident, and there appear multiple circular bodies with a central dot. These bodies measure only 0.0015 mm. in diameter, and are seen with great difficulty.

The intranuclear bodies represent the second stage in the life history, which is believed to be the sexual cycle, and produce spores which are the infecting agents. In the opinion of these authors the first cycle may exist without the second, and such is the case in vaccinia.

Apparently these are the same structures seen by L. Pfeiffer, Guarnieri, and others, who were not successful in working out the life history as it now stands, although they also did not hesitate to bring them into etiological relation to smallpox. One of the most recent of these (Govini) has even described and figured both extranuclear and intranuclear bodies in vaccinia. Questionable intranuclear bodies have also been reported by several investigators for sarcoma cells in man, but there are also other parasites belonging to this group and affecting lower animals in which an intranuclear existence is well known, *e.g.*, *Eimeria salamandræ* (= *Caryophagus salamandræ*), parasitic in the intestinal epithelium of one of the salamanders, and most frequently in the nucleus of the cell parasitized.

Hæmatozoa have been described by various authors as characteristic of beri-beri or kakki, an endemic form of polyneuritis particularly prevalent in Japan and the Dutch East Indies. The infectious nature of this disease seems to be generally accepted, and at different times various forms of possible pathogenic significance have been reported from the blood. The most recent of these are amœboid bodies resembling malarial parasites, which have been studied and described at length by Glogner, and especially Fajardo. The latter demonstrates their presence in the blood in peripheral as well as inner organs, and their production of pigment and formation of spores of some sort; and yet the possible confusion with malarial or other hæmatozoa and the lack of proof concerning the distinct etiological relation to beri-beri have prevented any general acceptance of the rôle assigned to the organism.

In leukæmia also Löwit claims to have discovered amœboid organisms in the leucocytes, and to have followed their development even to sporulation, *i.e.*, schizogony. (For further details see *Leukæmia.*) The parasitic nature of such structures cannot be regarded as established until they have been studied in life and not merely in preparations of fixed blood.

In dengue, an infectious disease epidemic in hot climates, and treated at length in an earlier volume (*q.v.*) good evidence has recently been furnished that the cause is a protozoön analogous to the malarial organism, and like it transmitted by the mosquito. It is an unpigmented pyriform body found in the erythrocytes though not abundantly, and is present in second and third attacks as well as in the first. The development is slow, requiring four to eight or even ten days, and in general appearance the organism suggests *Piroplasma bigeminum* of Texas fever in cattle or the organism of spotted or tick fever in man noted above. The discoverer, Graham, also found spores in the walls of the stomach and salivary glands of the mosquito, though this portion of the life history has not yet been clearly described; in one case the time required for it was, however, only forty-eight hours. In this case it is *Culex fatigans* which harbors the organism and transmits it, although other species may also be responsible. Graham has recently reported inoculation experiments, the results of which leave little doubt as to the cause of the disease and the method of transmission.

A long series of contributions concerns objects of supposed protozoan character which have been brought into etiologic connection with various pathological conditions by investigators of the most diverse type. Such are the pseudococcidia of epitheliomata, of sarcomata, of molluscum contagiosum, etc. Three views obtain as to the nature of these bodies, according to which they are blastomycetes or myxomycetes, sporozoa or other protozoa, and finally degenerative cell products. It cannot be said that their animal nature has been at all clearly demonstrated, and beyond the mere mention they have no right to consideration in this article.

In the subclass Neosporidia are included forms which in the adult condition are multinuclear, and which produce spores during the entire vegetative period. Spore formation is very characteristic. The organism forms a number of pansporoblasts, which divide again to form sporoblasts. The latter acquire a membrane and transform themselves with somewhat complicated changes into sporocysts, each of which develops within itself only a single sporozoite. Of the two orders only the

Sarcosporidia are of importance here, and they are but imperfectly known.

The Sarcosporidia possess an oval, elongate, or sacculate body (Fig. 5189), in which pansporoblasts are formed at a very early period. They parasitize at first intracellularly the muscle fibres, but by the degeneration of these come to lie in connective tissue and develop to oval or spherical bodies of considerable size. In the youngest stages yet found uninuclear spheres 0.004–0.005 mm. in diameter with relatively large nuclei (0.002–0.003 mm.) occur in the endoplasm. The protoplasm forms a frame-work between these young pansporoblasts, which increase in size with age and become also multinuclear. While at the ends of the sacculate body new pansporoblasts are continually being formed, in the older ones nearer the centre the contents divide into many finely granular pale spheres, the sporoblasts.

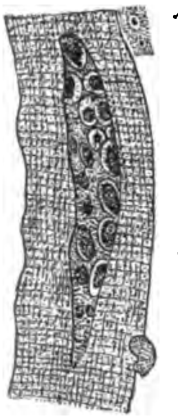

FIG. 5189.—*Sarcocystis tenella.* Longitudinal section of young stage with newly formed uninuclear pansporoblasts. Magnified. (From Wasielewski, after Bertram.)

In each of the latter is formed a single sporozoite which gradually assumes the definitive form (Fig. 5190, *a–d*). These sporozoites are usually reniform, sickle-shaped, or crescentic and very small. Some investigators claim to have discovered a polar capsule, and this has been partly confirmed by some later observers. Polar filaments are present in some cases (Fig. 5191, *b*). Theobald Smith has observed the movements of the sporozoites, and finds that in *Sarcocystis muris* there is a peculiar gliding with sudden revolutions on the long axis. This is carried out without the assistance of flagella. Smith's experiments, which were very painstaking and extended over three years, demonstrate for this species direct infection by feeding muscle tissue in which was present the parasite with ripe, mobile sporozoites. Sarcosporidia are parasitic in vertebrata, chiefly mammalia, and are common in many domestic animals.

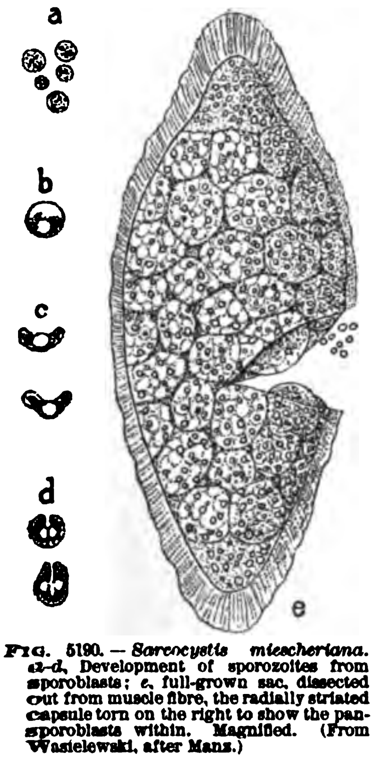

FIG. 5190.—*Sarcocystis miescheriana.* *a–d*, Development of sporozoites from sporoblasts; *e*, full-grown sac, dissected out from muscle fibre, the radially striated capsule torn on the right to show the pansporoblasts within. Magnified. (From Wasielewski, after Mans.)

Miescher in 1848 found these parasites first as cylindrical sacs in the voluntary muscles of the house mouse. Some years later Rainey found similar structures in the muscles of the pig, and the common names of these structures, often visible to the naked eye, are associated with these two investigators. The group has been but little studied, and the system is so imperfectly developed that it is advisable to omit all further mention of it, and to pass at once to a consideration of the one species which has been certainly obtained from the human body.

Sarcocystis Lindemanni (Rivolta 1878).—(Syn.: *Gregarina Lindemanni* Rivolta 1878; *Sarcocystis hominis* Rosenberg 1892; *S. Lindemanni* Labbé 1899.)

Protoplasmic body from the muscle fibres of the vocal cords, from 0.15 to 1.6 mm. long and from 0.077 to 0.17 mm. thick; membrane delicate, somewhat thickened at the ends (Fig. 5191, *a*), body distinctly chambered (Fig. 5191, *e*). Sporozoites (*d*) banana shaped, exceedingly numerous, 0.008–0.009 mm. in length.

The most certain case is that of Baraban and St. Remy, who found this form in the body of a criminal executed at Nancy. All the specimens of the parasite were in the same stage of development. The infected muscle fibres were swollen to fourfold their normal thickness. Several other uncertain cases are on record. As Theobald Smith remarks, the muscular system is not subject to the scrutiny which the viscera undergo in pathological investigations, so that the presence of these forms may be much more frequent and important than appears as yet. In the case of *S. muris* Smith has shown that the feeding of muscle tissue containing ripe mobile sporozoites to gray and white mice is followed by an invasion of the muscle fibres by the parasites, which readily become recognizable after the forty-fifth day. Nothing is known regarding the development of *S. Lindemanni.*

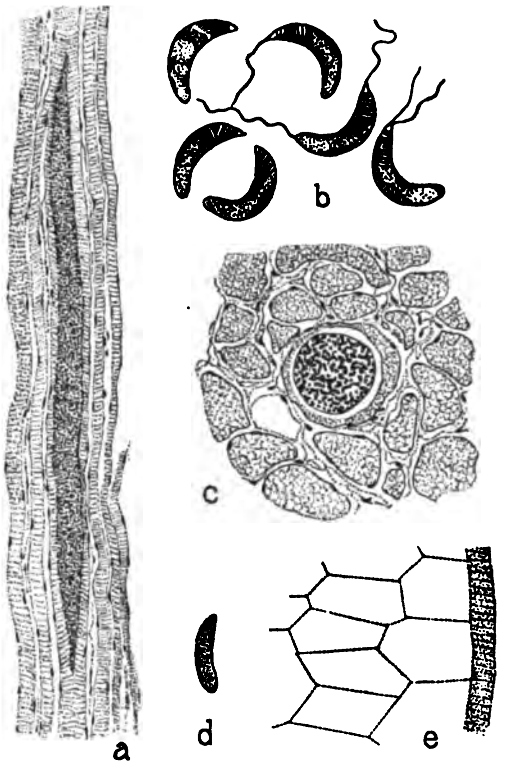

FIG. 5191.—*Sarcocystis Lindemanni* from Human Larynx (except *b*). *a*, Longitudinal section of muscle fibre with fully developed sac. × 250. *c*, Transverse section of same. × 250. *e*, Section showing chambers emptied of pansporoblasts. × 565. *d*, Sporozoite. × 1,350. *b*, Sporozoites of *S. Blanchardi* with polar filaments. × 875. (*b*, From Wasielewski, after van Ecke; other figures from Doflein, after Barbaran and St. Remy.)

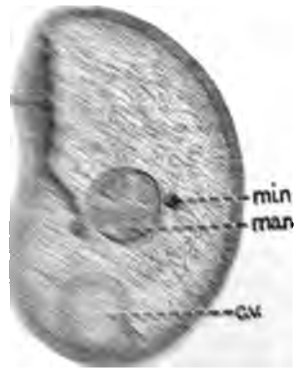
The class Infusoria holds the highest rank among Protozoa, and its members are at once distinguished by the presence of peculiar organs of locomotion in the form of fine hair-like protoplasmic processes, the cilia, which are present in at least some part of the life history of all individuals in the group. By virtue of the greatly inferior length, the much larger number present on each animal, and the simple synchronous movement cilia are easily distinguished from flagella. The external zone or ectoplasm is more highly differentiated than in the forms of [illegible] thus far considered, and the body has in consequence a more permanent form, which tends to acquire in all free species a bilaterally symmetrical structure. In the ectoplasm one finds special contractile fibrils, or myonemes, and peculiar unexplained bodies known as trichocysts. The cilia are arranged in rows, and occasionally fuse into vibrating membranes or stylet-shaped plates, etc., in furtherance of the motor function. The [illegible] forms at the mouth opening (cytostome) a groove (peristome), or a peculiar funnel-shaped pit (cytopharynx), which serves to admit food particles to the interior of the body. A differentiated anal orifice (cytopyge) is very rarely found. The contractile vacuole is always present, and often two or more occur with a more or less complicated canal system branching in all directions.

One of the most striking peculiarities is found in the nuclear conditions. Typically two nuclei are present; a large vegetative nucleus or macronucleus, and a small sexual nucleus or micronucleus, which usually lies close to the former. The macronucleus is always single, but there may be several micronuclei to each cell. The ordinary process of reproduction is fission or gemmation, and in this the macronucleus divides amitotically while the micronucleus undergoes indirect or mitotic division. At times one finds conjugation, or temporary and partial fusion of two individuals with the destruction of the macronucleus and of a certain portion of each micronucleus, while the remainder of each micronucleus on each side is divided equally between the two individuals. From the portions of the micronuclei fused there arise new macronuclei and micronuclei. This process has generally been looked upon as one of rejuvenation, and necessary for the continued existence and reproductive power of the individual. Certain recent investigations leave this somewhat uncertain. The complicated details of the process find, however, an evident parallel in changes connected with the fertilization of higher forms, in the union of egg and sperm cells.

Encystment is frequent, and the evident means of pro[illegible] unfavorable changes in environment, such as drought, temperature changes, etc. In parasitic forms [illegible] to the necessary interval of transport to a new host. In the majority of cases these protozoa are commensals rather than true parasites, and in some instances are even said to be of mutual advantage to the host, and consequently symbiotic in character. The two subclasses are distinguished on the basis of the permanence of the ciliary covering which is constantly present in the Ciliata, save during encystment, but which is found only in the young forms of the Suctoria. The latter are also supplied with peculiar sucking tubes for taking in nourishment. They do not furnish any forms found in the human body.



[illegible] Living. [illegible] vacuole; man., [illegible] macronucleus; Magnified. (After [illegible]

The Ciliata are present in large numbers in all fresh-water bodies, and manifest great variety of structure. They furnish many ectoparasitic species on water-living vertebrates and a few endoparasitic in higher forms, including man. The various orders into which the Ciliata are divided are based upon the number and arrangement of the cilia in the adult form.

[illegible] orders call for attention here. In the [illegible] is no spiral zone of prominent cilia or [illegible] leading to the cytostome, and the body [illegible] small cilia which are more or less generally distributed. The Heterotricha have an adoral spiral zone of larger cilia, but the remainder of the body is uniformly finely ciliated.

Of the Holotricha one species has been reported from man. It belongs to the genus *Chilodon*, the distinctive features of which are included in the description of the species which follows.

Chilodon dentatus (Dujardin 1841).—(Syn.: *Loxodes dentatus* Duj. 1841; *Ch. dentatus* Guiart 1903.)

Oval, 35–55 μ long by 25–35 μ broad, flattened in ventral face, dorsal aspect strongly arched. Anteriorly a flexible membranaceous projection curved toward the left and carrying several rows of cilia on the lower aspect. Granular endoplasm confined to posterior inflated region; ectoplasm in a thin peripheral layer and forming the anterior projection. Mouth ventral, in anterior portion of the endoplasmic region, normally contracted and hardly visible, cytopharynx directed dorsally and recurved ventrad so as to form almost a complete circle. Two contractile vacuoles, macronucleus large, spherical, in posterior region.

This infusorian has been found once by Guiart, as a parasite of the human intestine in Paris, France. The animals were present in large numbers in the mucus from dysenteric stools. Care was taken to control the source of the parasite and to avoid contamination from external sources, with the result of obtaining from the dejecta on the second day after passage pure cultures of the infusorian. It is a common free-living species, and must be classed in this instance merely as an accidental parasite. Close examination of fæcal discharges will undoubtedly show the occasional occurrence of many such, especially when the resting spores happen to be abundant in the local supply of drinking-water. In this case there is nothing to show that the resting spores did not simply make the passage of the canal, and then develop almost at once in the discharges. The extreme sensitiveness of the species to changes in the environment, which has been commented upon by Guiart himself, makes this explanation of the case more probable. One should recall in this connection the record of Schaudinn, that the resting spores of a Rhizopod, *Chlamydophrys stercorea*, must make the passage of the alimentary canal in man or other animals in order to undergo development. In this case, indeed, the resting spores open in the colon and an amœboid organism emerges which does not assume the testaceous form of the adult until after the fæces are discharged from the body.

The order of the Heterotricha, already generally characterized, includes three species under two genera, which have been reported from the human host. The first belongs to the genus *Nyctotherus* Leidy 1849, which contains flattened reniform species with a peristome along the concave side from the anterior pole to the cytostome at the centre. The cytopharynx is more or less arcuate. The macronucleus is large and nearly central in location. A single contractile vacuole is present. The species of this genus occur as parasites in the alimentary canal of Anura, Myriapoda, and Insecta. A single form has been found twice in the human alimentary canal.

Nyctotherus faba Schaudinn 1899.—Body reniform, somewhat flattened dorsoventrally, left side convex, right concave and notched in the centre. Anterior end bent to the right a little, and on the right side slightly cut out; posterior end broadly rounded (Fig. 5192). Length 0.026–0.028 mm., breadth 0.016–0.018 mm., thickness 0.01–0.012 mm. Peristome a narrow longitudinal slit just at right margin of body, extending from near anterior end to middle of body. Cytopharynx tubular, short, and without guide spine at entrance. Cilia very fine and delicate as well as short. Ectoplasm thin, endoplasm granular, alveolar and without food vacuoles. Contractile vacuole large, located left of middle, near posterior end, emptying through the special anal tube. Macronucleus spherical, 0.006–0.007 mm. in diameter, with chromatin in four or five solid masses near periphery, leaving the intervals filled by a non-staining linin network. Micronucleus 0.001–0.0015 mm. in diameter, spherical or oval, ordinarily next the macronucleus. Fission and conjugation were not observed. Encysted form oval, easily recognized by the strange macronucleus.
